Chapter 4: Urine in urinary tract lesions	84
Chapter 5: Urine in non-neoplastic renal parenchymal diseases	114

PREFACE

This monograph *“Essentials of Fluid Cytology”* is written for practicing pathologists in community hospitals, residents in pathology and cytotechnologists who want to have a quick review of the cytopathology of serous effusions, peritoneal and pelvic washings, cerebrospinal fluid and urine in neoplastic and non-neoplastic diseases of the kidney and lower urinary tract. Cytologic manifestations of lesions commonly encountered in day-to-day practice are discussed and illustrated. In keeping with the goals of the author’s cytology monograph series, the text is concise and contains only relevant information. Immunohistochemical features of neoplasms that are important for tumor typing and differential diagnosis are stressed. And for most lesions, cytologic and histologic images are presented side by side for easy comparison.

For improvement of the future editions of this monograph, comments and suggestions from the reader will be highly appreciated.

ACKNOWLEDGEMENTS

I wish to thank Dr. Jason Ford and Mrs. Helene Dyck of The David Hardwick Pathology Learning Centre, Vancouver, BC, Canada for their enthusiasm and effort in publishing this monograph "Essentials of Fluid Cytology". Their superb work is highly appreciated.

I also want to thank my dear family members, in particular my wife Ho thi Nga, for their continued moral support over the years.

Gia-Khanh Nguyen, M.D.

Serous Effusions

Gia-Khanh Nguyen and Thomas A. Thomson

The history of serous effusion cytology can be traced back to the 19th century. Lucke and Klebs were apparently the first investigators who recognized the presence of malignant cells in an ascitic fluid in 1867. In 1882 Quincke was credited for detailed descriptions of ovarian and lung cancer cells in serous effusions. Since that time reports on effusion cytology have started to appear in the medical literature, and serous effusion cytology now is a routine diagnostic procedure worldwide. In recent years, with the availability of several commercially available antibodies, diagnosis and typing of malignant cells in serous fluids has become more reliable, obviating the time-consuming and expensive electron microscopic examination of effusion cell blocks.

COLLECTION AND PREPARATION OF CELL SAMPLES

For effusion cytology a proper collection and preparation of cell samples are the prerequisites for a reliable cytodiagnosis. Serosal fluid samples are obtained by needle aspiration or evacuation of symptomatic pleural, pericardial or peritoneal effusions to relieve dyspnea or discomfort. A minimum sample of 20 mL and larger volumes are desirable for cytologic study. A liter of effusion can yield 0.5-1mL of sediment for cell block (CB) preparation.

1. Routine preparation. Fixative is not necessary and there is no significant alteration of cell morphology noted if the specimen is processed within 12 hr or kept refrigerated at 4^o C up to 72 hr. When a longer delay is anticipated, addition of an equal volume of 50-95% ethanol or Saccomanno fixative (50% ethanol and 2% carbowax) is recommended. Addition of a vial of heparin to fluid a sample will prevent protein precipitation by ethanol, as clotting of a protein-rich effusion interferes with specimen processing. Routinely, 4 cytologic preparations (usually called smears) are made by direct smearing of fluid sediment or by cytocentrifugation. The smears are either fixed in 95% ethanol or air-dried. Fixed smears are stained by the Papanicolaou technique, with hematoxylin and eosin, and air-dried smears are stained with the Romanowsky technique or one of its modified methods (Wright, MGG or Diff-Quik methods). Red blood cells in a bloody smear may be lysed by fixing in Carnoy solution for 3-5 min. A Ficoll- Hypaque solution may be used to separate red blood cells from nucleated cells in a markedly bloody specimen. The CB obtained by centrifugation is fixed in formalin and processed as a tissue sample and CB sections are routinely stained with hematoxylin and eosin.

3. Immunocytochemical staining may be performed on air-dried, ethanol-fixed or formalin-fixed smears. For smears already stained by the Papanicolaou method, destaining with acid-alcohol is not necessary prior to IM staining. Histologic sections from a formalin-fixed CB are the most suitable specimens for IM study by the routine ABC technique.

4. Electron microscopy. A small portion of about 2 cubic mm of effusion sediment obtained by centrifugation of a fresh and unfixed fluid sample is fixed in 2% glutaraldehyde and processed as a tissue fragment for transmission electron microscopic (EM) examination. Unfixed specimens kept refrigerated at 4° C usually preserve cell morphology for EM study for about 48 hr. Formalin-fixed and paraffin-embedded CB can be de-waxed and processed for EM study. Ethanol is not a suitable fixative for this purpose as it destroys cellular ultrastructures.

5. Delay in processing of fresh fluid samples kept in a refrigerator at 4° C up to 14 days does not cause any remarkable alterations in morphology and IM or molecular characteristic features of suspended tumor cells, according to Manoska et al. Therefore, residual fluid samples should be stored in refrigerator for additional diagnostic procedures, if indicated.

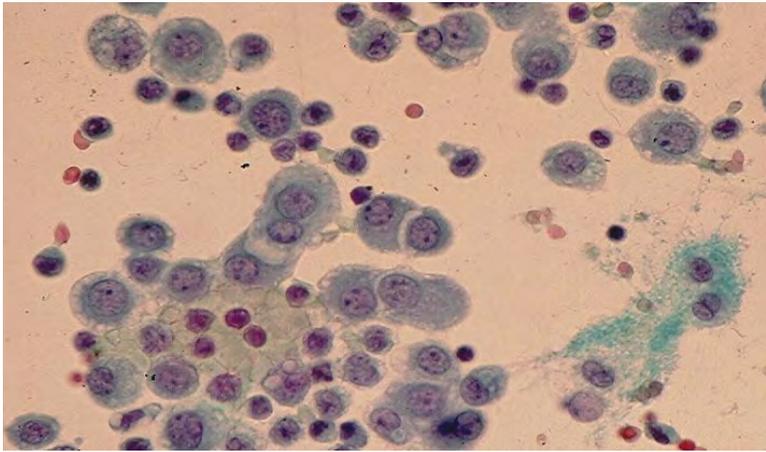

TRANSUDATE AND EXUDATE

In healthy individuals the pleural, peritoneal and pericardial cavities are lined by a single layer of mesothelial cells and contain a small amount of serous fluid. Serous effusions occur when an excessive amount of fluid accumulates in these cavities. Serous effusions are traditionally classified into two types: transudate and exudate.

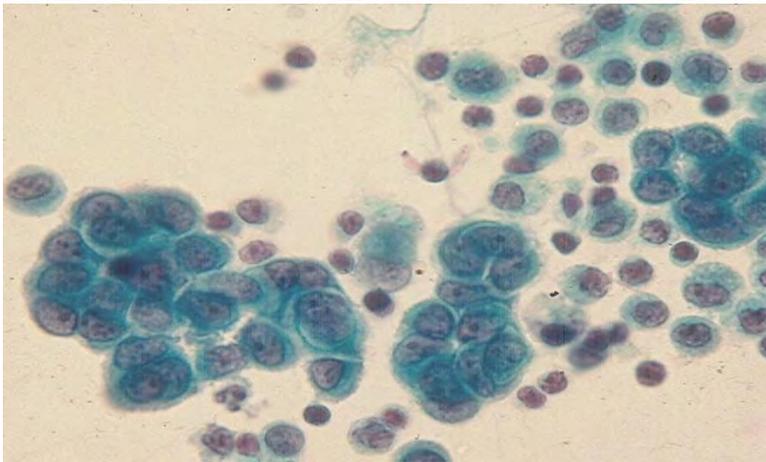

Transudate is caused by changes in osmotic pressure. The most common causes of transudate are congestive heart failure and hypoproteinemia (cirrhosis, renal failure). A transudate has a straw-colored appearance, a specific gravity < 1.010, protein contents < 30g/L and a fluid LDH: serum LDH ratio <0.6. It shows a few mesothelial cells and lymphocytes in routinely stained cytologic preparations.

Exudate is caused by damage to capillary blood vessel walls. The most common etiologies of exudate include malignancy or inflammation due to infection, acute pancreatitis, pulmonary infarction, chemotherapy and radiotherapy. An exudate is turbid, purulent or bloody in appearance and has a specific gravity >1.010, protein contents >30g/L and a fluid LDH: serum LDH ratio > 0.6. Cytologically, an exudate contains polymorphonuclear leukocytes, lymphocytes and mesothelial cells. In patients with malignant tumor involving a serosal cavity the associated effusion usually contains numerous cancer cells.

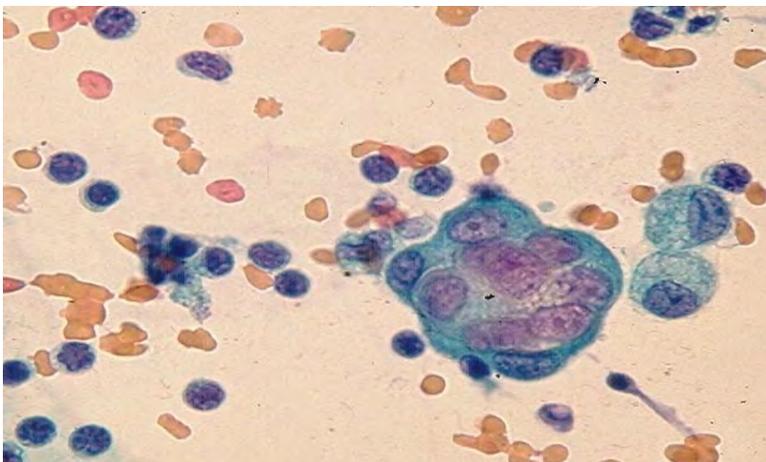

An atypical mesothelial cell proliferation is common in a chronic or long-standing serous effusion. This may be secondary to cirrhosis, chronic inflammatory lung diseases, pulmonary infarction, radiotherapy, chemotherapy, collagen vascular diseases or trauma (e.g. from chest injury or thoracotomy). The fluid sample usually contains a large number of single and clustered hyperplastic mesothelial cells. Rarely these mesothelial cells form large tridimensional, ball-like clusters with some cellular atypia mimicking malignant cells. (Fig. 1.1).

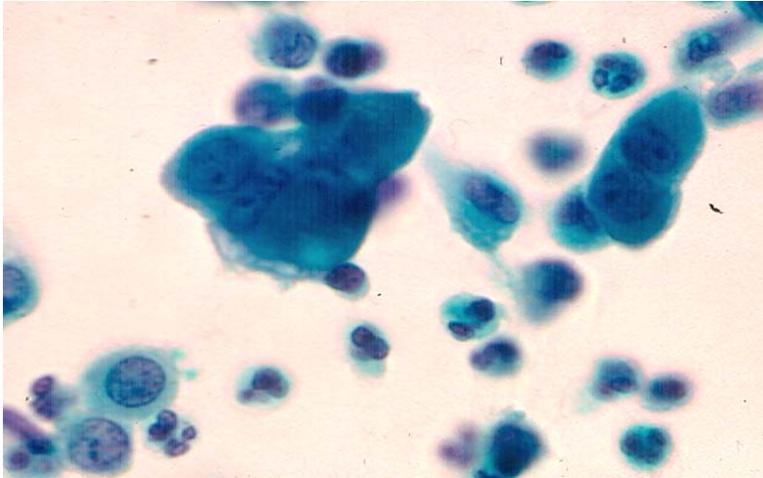

A

B

C

D

Fig. 1.1. Atypical mesothelial cell proliferation. (Pap, x 400):

- A. Hyperplastic mesothelial cells with slightly enlarged nuclei, micronucleoli and a clear space or "window" between adjacent cells, present singly and in small clusters.
- B. Larger clusters of hyperplastic mesothelial cells showing mildly nuclear atypia with small nucleoli. Small clear spaces between adjacent cells are present.
- C. A tight cluster of atypical mesothelial cells with prominent nucleoli.
- D. A cluster of highly atypical mesothelial cells showing pleomorphic nuclei, prominent nucleoli and slight nuclear molding.

The presence of large tridimensional clusters of epithelial-like cells in a pleural effusion is suggestive of a malignant disease (metastatic adenocarcinoma or mesothelioma). Reactive mesothelial cells with nuclear atypia (RAMC) may mimic cancer cells from a mesothelioma or adenocarcinoma. Clustered RAMCs commonly show tight cell junctions and a clear space or "window" between adjacent cells. RAMCs rarely form large ball-like clusters in pleural effusions but large cell clusters are more commonly observed in peritoneal and pericardial effusions. The differential diagnosis between RAMCs and mesothelioma cells or malignant glandular cells is problematic in routinely stained smears. IM study is helpful in distinguishing RAMCs from adenocarcinoma cells but has no practical value in separating RAMCs from mesothelioma cells as these 2 cell types share a common phenotype (positive for calretinin, CK5/6, mesothelin and Wilms tumor gene product 1 (WT1) and negative with CEA, MOC31 and Ber-Ep4 antibodies). Malignant glandular cells usually have the inverse phenotype: positive for CEA, MOC31 and Ber-Ep4 and negative for calretinin, CK5/6, mesothelin and WT1. According to some studies staining with p53 antibody may be useful in distinguishing RAMCs from mesothelioma cells as malignant cells may express p53 and reactive cells may not. Some investigators have found that RAMCs react weakly or negatively with EMA antibody while mesothelioma cells show a strong membranous reaction. According to Saleh et al. malignant effusions have a Ki-67 (MIB1) immunostain labeling index value > 20% in 82% of cases while the index value of benign effusions is <5%. In equivocal cases, biopsy of serosal lesions for histologic evaluation is necessary.

NEOPLASTIC DISEASES

The serosa lining a body cavity can harbor an epithelial or non-epithelial malignancy. The most common cancer involving a serosal cavity is a metastatic cancer. Among primary malignant tumors of the serosa, mesothelioma is the most important one.

A. MESOTHELIOMA

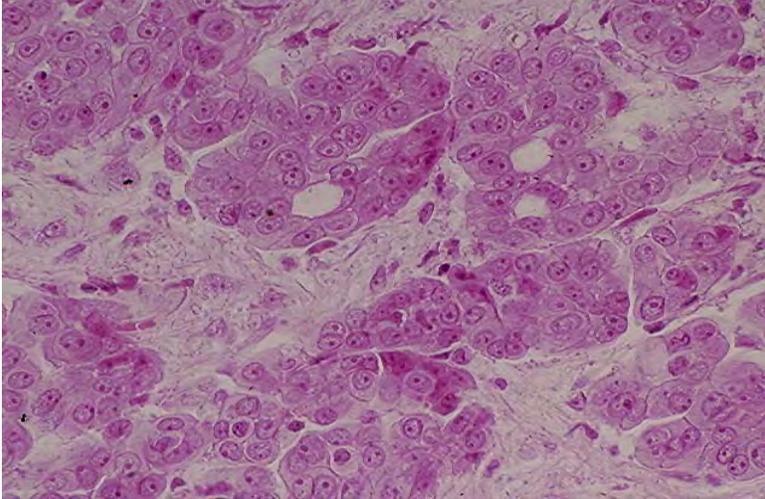

Malignant mesothelioma, also known as mesothelioma, is a rare malignant serosal neoplasm that is commonly related to occupational asbestos exposure. Other potential etiologies include chronic inflammation, organic chemicals, non-asbestos mineral fibers, irradiation and genetic factors. About 75% of patients are men between 50-70 years of ages, and almost all patients die of the disease within 6-12 months after the diagnosis. Mesothelioma most commonly arises in the pleural cavity. Peritoneal mesothelioma accounts for 1-10% of all cases, and the tumor rarely arises in the pericardium or tunica vaginalis.

Histopathology, Immunohistochemistry and Ultrastructure

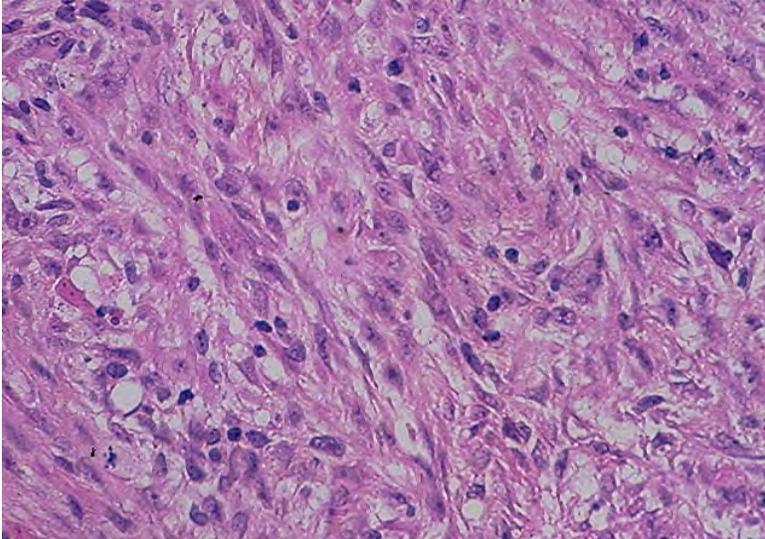

Four main histologic types of mesothelioma are encountered: epithelial, sarcomatous, desmoplastic and mixed tumors. Epithelial mesothelioma (EM) is the most common tumor type, accounting for about 50% of all cases while sarcomatous and mixed mesotheliomas account for 15-20% and 25-30% of cases, respectively.

Histologically, an EM consists of tumor cells with variable degrees of anaplasia arranged in tubulopapillary, adenomatoid (microglandular) or solid pattern. Four rare histologic subtypes of EM are adenomatoid, deciduoid, small cell and clear cell mesotheliomas. A sarcomatous mesothelioma is characterized by spindle malignant cells arranged in a nonspecific pattern. A mixed mesothelioma is composed of epithelial and sarcomatous elements and areas showing a transition between these two cellular elements may be observed. (Fig.1.2 and Fig.1.3)

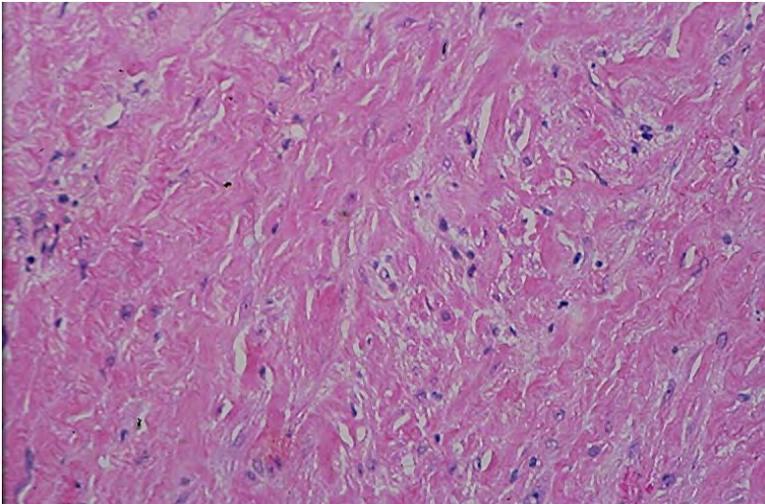

By IM, EM cells usually stain positively for pan cytokeratins, CK5/6, vimentin, calretinin, podoplanin (D2-40), HBME, EMA and WT1 and react negatively with epithelial antibodies such as CEA, MOC31 and Ber-Ep4. Sarcomatous mesothelioma cells usually express vimentin and cytokeratin. By electron microscopy, cells of an EM show desmosomes, intracytoplasmic and perinuclear bundles of intermediate filaments and numerous filamentous microvilli without dense core rootlets and with a length:diameter ratio >12, and intracytoplasmic mucous granules are not identified.

Cytology of mesothelioma

Epithelial and mixed mesotheliomas account for about 90% of all pleural and peritoneal primary tumors. Both neoplasms are commonly associated with a serous effusion. Sarcomatous and desmoplastic mesotheliomas are usually not associated with an effusion. Serous effusions in patients with epithelial and mixed mesotheliomas are usually cellular and show numerous EM cells that often display a wide range of nuclear changes, ranging from mild to marked atypia to frank malignancy. In about 10% of cases the effusions are acellular or contain only rare benign reactive mesothelial cells. Sarcomatous cells in a mixed mesothelioma and cells of a sarcomatous or desmoplastic mesothelioma do not usually and spontaneously exfoliate into associated effusions.

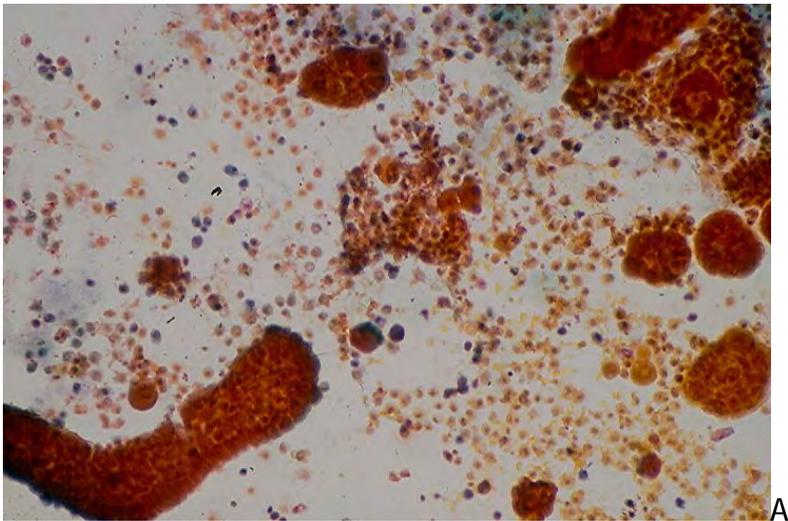

The cytodiagnosis of EM in serous effusion requires first to cytologically diagnosis malignancy and then to identify mesothelial features/differentiation of the cancer cells present.

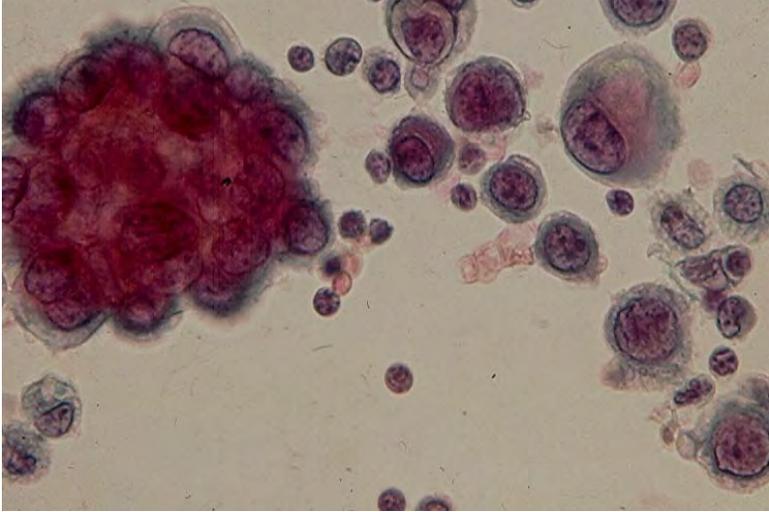

In about 50% of cases, cells from an epithelial or mixed mesothelioma occur singly, in small groups and in large tridimensional ball-like clusters consisting of up to several hundreds cells. In about 25% of cases the tumor cells occur predominantly in tridimensional clusters with very few cells present singly and in small clusters. In the remaining 25% of cases the tumor cells occur predominantly singly.

From the cytodiagnostic point of view an EM can be suspected in about 60% of cases by examination of routinely stained cytologic preparations. Classic cytologic manifestations of an EM consist of malignant cells showing the following features. (Fig. 1.4- Fig. 1.7):

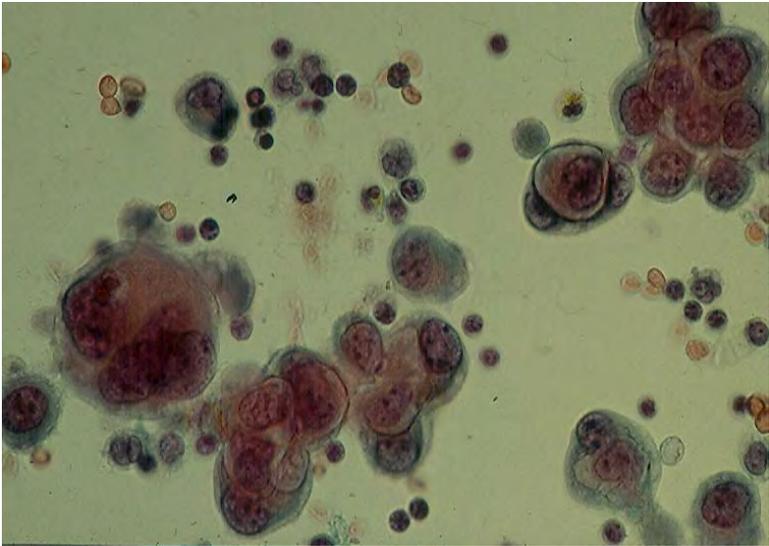

- **Tumor cells occur singly, in small groups or clusters**, as well as in large tridimensional clusters (>50 cells). Large cell clusters have smooth and lobulated contours.
- **Tumor cells are usually large and resemble normal mesothelial cells** except they have larger nuclei, prominent nucleoli and show a **spectrum of nuclear changes ranging from benign to atypical to malignant**. The presence of two distinct cell populations, one benign and the other malignant, as seen in metastatic cancers, is not obviously present.
- Small tumor cell clusters commonly show **"cell-embracing-cell" , "push-in" cell junctions and a clear space or "window" between two adjacent cells**.
- **Thick papillary tumor tissue fragments** with or without fibrovascular cores may be seen and are highly suggestive of an EM.
- **Tumor cells have a thick endoplasm and a fuzzy ectoplasm** that is due to the presence of long filamentous microvilli on free cell surfaces.

An *adenomatoid mesothelioma* may exfoliate cells with extensive cytoplasmic vacuolization, mimicking cells from a mucus-secreting adenocarcinoma or signet-ring cell carcinoma. (Fig.1.8).

Cell block. CB from an effusion secondary to an EM may reveal papillary tumor tissue fragments with fibrovascular cores covered with a single layer of tumor cells. This rare and interesting finding is highly suggestive of an EM. (Fig.1.9).

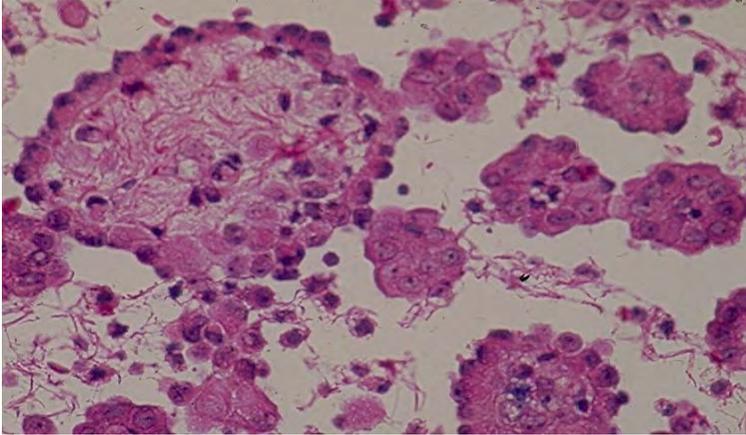

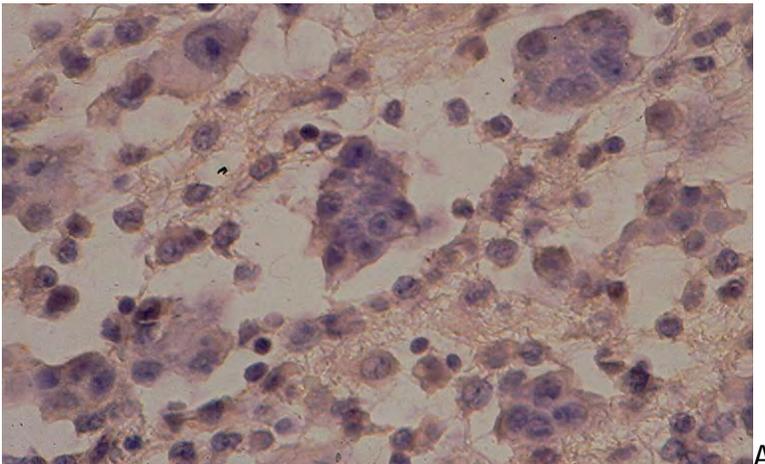

Fig.1.9. Papillary tumor tissue fragments in a CB section prepared from serous effusion associated with a pleural EM. (HE, x 250).

Immunohistochemistry

Because in the majority of cases the cytologic manifestations of an EM mimic those of a metastatic adenocarcinoma to the serosa, it is important to rule out, by IM studies, an adenocarcinoma. Important IM characteristic features of EM cells consist of a lack of expression of epithelial antigens such as CEA, MOC31, Ber-Ep4 and the presence of mesothelioma antigens such as HBME-1, calretinin, CK5/6, podoplanin and WT1. According to Ordonez, a combination of 2 positive markers (calretinin, CK5/6, WT1) and 2 negative markers (CEA, MOC31, Ber-Ep4) is adequate for a firm diagnosis of EM. (Fig.1.10).

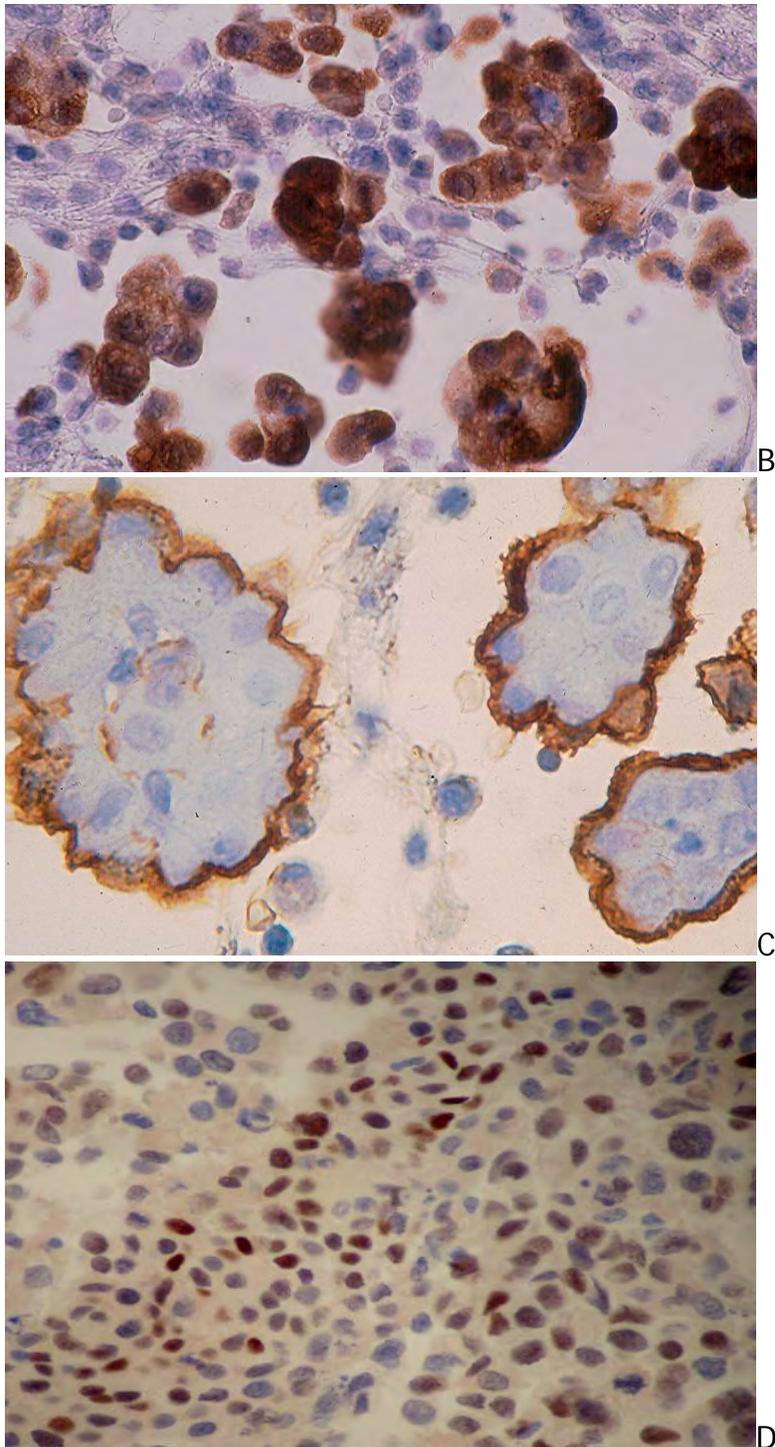

Fig.1.10. Immunohistochemistry of effusion CB in EM:

- A. Tumor cell cytoplasm reacts negatively with CEA antibody. (ABC, x 250).
- B. Tumor cells show strong cytoplasmic reaction to calretinin antibody. (ABC, x 250).
- C. Strong, thick, membranous positive staining with spiking pattern with EMA antibody, reflecting the presence of long microvilli on tumor cell surfaces (ABC, x 250).
- D. EM cells showing positive nuclear staining to WT1 antibody (ABC, x 250).

Cytodiagnostic accuracy

Cytodiagnostic accuracy of EM in reported series varies widely, ranging from 32% - 93%, according to the literature review by Whitaker et al. In Whitaker's experience, with adequate IM study, a cytodiagnostic accuracy of mesothelioma as high as 80% may be reached, and the predictive value of a positive diagnosis of mesothelioma in serous effusions is 100%. With reliable commercial antibodies, electron microscopic study of effusion CB now is rarely necessary to identify mesothelioma cells. However, when IM results are equivocal, ultrastructural study of the tumor cells is needed for further confirmation. For a more comprehensive discussion on value and limitations of different antibodies used in the IM diagnosis of mesothelioma the reader is referred to the 4 articles by Ordonez, Leong and Vernon-Roberts, Suster and Moran and Husain et al.

B. PRIMARY EFFUSION LYMPHOMA

This large B-cell neoplasm presents as a serous effusion without detectable tumor masses. It is associated with human herpes virus 8(HHV8)/Kaposi sarcoma herpes virus (KSHV) and it usually occurs in patients with immunodeficiency. Most patients are young to middle aged homosexual males with HIV infection. However, cases with HIV-negative allograft recipients, particularly after cardiac transplantation, have been documented. The most common sites of tumor involvement are pleural, peritoneal and pericardial serosal cavities. Typically only one cavity is affected. The disease is highly aggressive and most patients died within one year.

Cytologically, the tumor cells in the effusion consist of dyshesive, large malignant lymphoid cells with immunoblastic features, prominent nucleoli and mitosis. (Fig.1.11). Markedly pleomorphic tumor cells may be observed in some cases. The cells typically express leukocyte common antigen (CD45), CD30 and plasma cell-related markers (CD38 and CD138), and they are usually negative for pan-B-cell markers such as CD19, CD20 and CD79a. The nuclei are positive for HHV8/KSHV-associated latent protein, and this expression confirms the diagnosis.

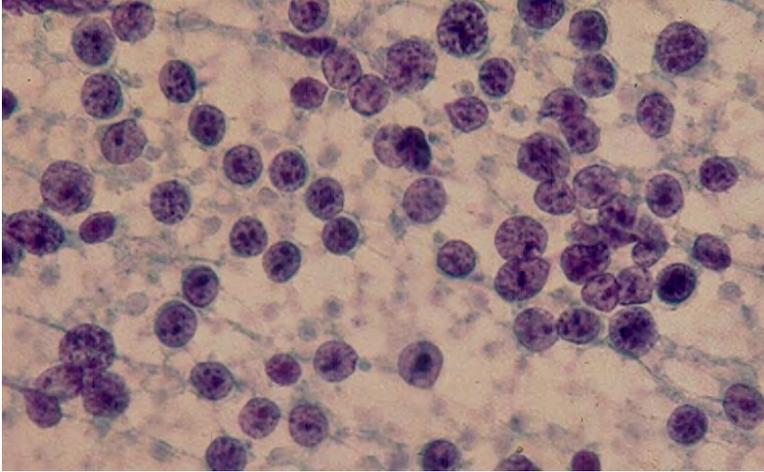

Fig.1.11. Malignant lymphoid cells with prominent nucleoli from a case of primary effusion lymphoma. (Diff-Quik, x 500).

C. METASTATIC CANCERS

The difficulty in cytodiagnosis of malignant effusion varies from case to case. If the primary cancer is known the diagnosis is usually straightforward. However, diagnosis of a metastatic adenocarcinoma of unknown primary by effusion cytology is often challenging and requires a careful clinicopathological correlation and extensive IM studies.

In men, malignant pleural effusions are most commonly caused by lung cancer, followed by lymphoma and gastrointestinal malignancies. In women, they are most frequently caused by metastatic breast cancer, followed in decreasing order by lung cancer, ovarian cancer and gastrointestinal cancer. In the United States, about 1% of malignant pleural effusions are caused by mesothelioma.

In men, malignant ascitis is most commonly caused by gastrointestinal cancer followed by lung cancer and lymphoma. In women ovarian cancer is the commonest cause followed by breast and gastrointestinal malignancies.

Malignant pleural effusion of unknown primary is most commonly secondary to a lung cancer in both men and women. In about 15% of malignant ascites the primary cancer is occult at initial investigation. Of these over 50% are caused by a clinically occult ovarian cancer in women. Cancers arising from the pancreas, gallbladder, prostate and urinary bladder are rarely associated with a malignant ascitis. Breast cancer is the most common malignancy in women and it rarely manifests initially as a pleural malignant effusion of unknown primary. Lymphoma, melanoma and mesothelioma may also present initially as a malignant pleural effusion of unknown primary.

Regarding the histologic types of malignant effusions, adenocarcinoma is the most common tumor followed by lymphoma, large cell carcinoma, squamous cell carcinoma, small cell carcinoma, mesothelioma and sarcoma. Diagnosis of a malignant effusion of unknown or occult primary is challenging but the identification of the primary tumor is now more successful thanks to advances in diagnostic imaging techniques and commercially available high-quality antibodies.

Cytologic Findings in Metastatic Cancers

Common cytologic features of most metastatic malignancies in serous effusions include increased cellularity and a distinct non-mesothelial population of enlarged cells that have enlarged nuclei with irregular nuclear contours, high nuclear:cytoplasmic ratio, coarse chromatin, multiple prominent nucleoli, increased mitosis, atypical mitosis and presence of tridimensional tumor cell clusters.

Routinely stained smears of malignant effusions with well-differentiated cancer may permit a proper classification of the cancer cells into 4 broad categories: epithelial, lymphomatous, melanocytic and sarcomatous malignancies. Among the carcinomas, tumor cells with squamous or glandular differentiation and anaplastic cancers of small and large cell types can be cytologically typed with confidence in the majority of cases. In the case of a poorly differentiated or undifferentiated cancer, IM studies are needed for a more accurate tumor typing. By staining with antibodies to S-100, HMB-45, AE1/AE3, calretinin, MOC31, CEA, LCA and vimentin, poorly differentiated cancer cells may be classified into 5 cell lines: lymphomatous, melanocytic, epithelial, mesothelial and sarcomatous. According to Dabbs, a coordinate staining of epithelial cells with CK7/CK20 antibodies will further divide them into 4 different categories, each with only a few cancer types.

1. CK7+ and CK20+: Urothelial carcinoma and ovarian mucinous carcinoma.
2. CK7+ and CK20-: Carcinomas of lung (small cell, non-small cell and non-squamous), breast, ovary (serous type), endometrium and thyroid; germ cell tumors and epithelial mesothelioma.
3. CK7- and CK20-: Squamous cell, prostatic, renal cell and hepatocellular carcinomas.
4. CK7- and CK20+: Colorectal and Merkel cell carcinomas.

Additional IM expressions of some cell markers by metastatic carcinoma cells may further confirm the anatomic sites of their primary cancers. These specific antigenic expressions will be mentioned in each carcinoma discussed below.

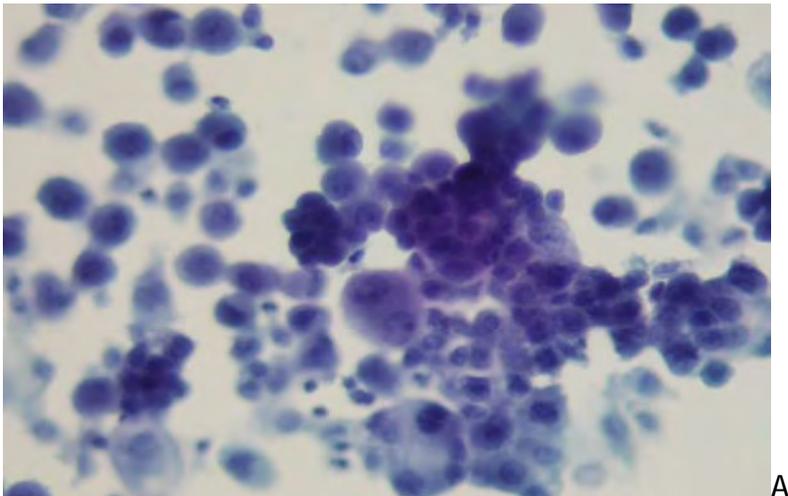

Carcinomas arising from certain anatomic sites may have some specific cytologic manifestations in serous effusions. However, cells exfoliated from metastatic adenocarcinomas often display considerable overlapping features. Therefore, IM studies are extremely important in these situations.

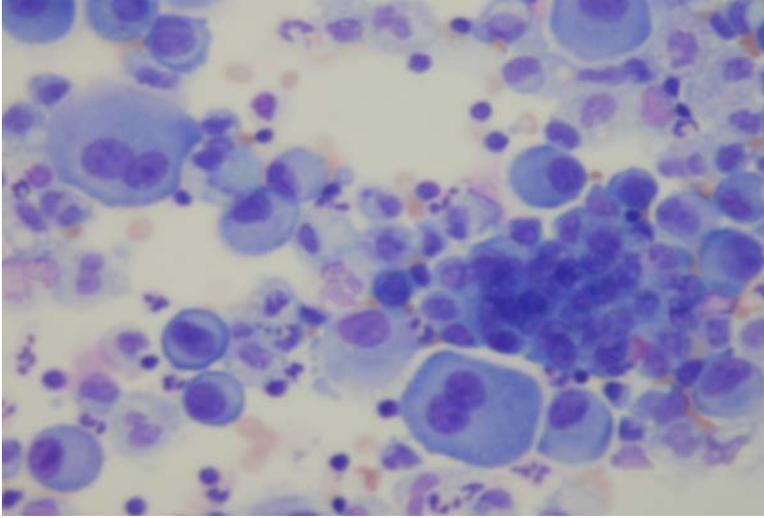

Malignant Epithelial Tumors

Bronchogenic Carcinoma

Bronchogenic cancers account for about 30% of all pleural malignant effusions, and adenocarcinoma is the most common tumor. Lung carcinoma (small cell and non small cell) cells express CK7, CEA and TTF1. Cells derived from a squamous cell carcinoma are an exception to those IM features although a small number of squamous cell carcinomas are CK7 positive.

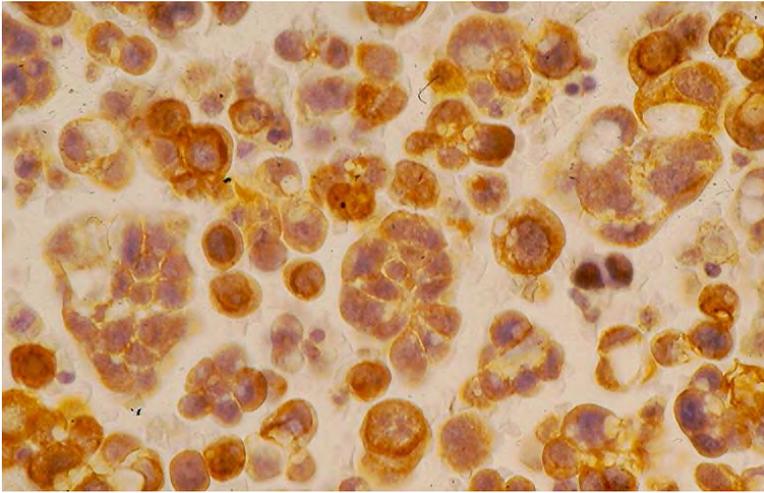

1. *Adenocarcinoma*. Cells exfoliated from a bronchogenic adenocarcinoma tend to occur singly and in irregular clusters and show prominent nucleoli, cytoplasmic vacuolization; and multinucleation may be seen. (Fig.1.12 and Fig.1.13)

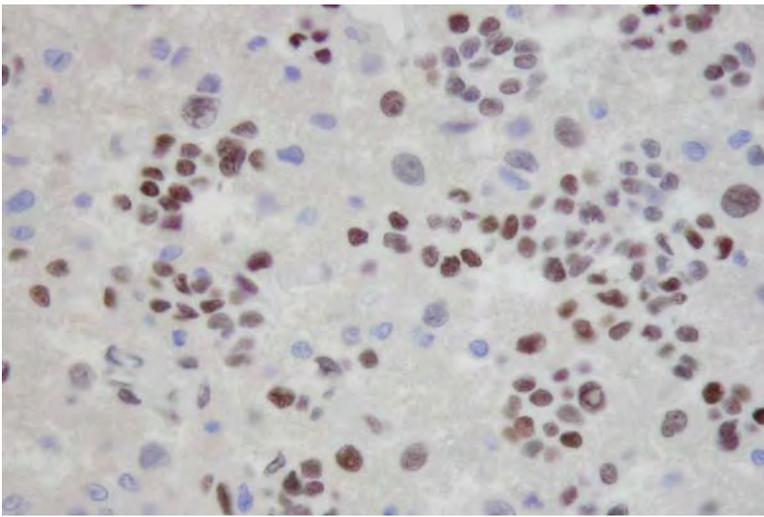

B

Fig.1.12. Pleural effusion in a bronchogenic adenocarcinoma showing single and clustered malignant glandular cells. (A: Pap, x 400; B: Diff-Quik, x 400).

A

B

Fig.1.13. Immunohistochemistry of bronchogenic adenocarcinoma:

A: Tumor cells in CB showing a strong cytoplasmic reaction to CEA antibody.
B: Tumor cell nuclei in CB stain positively with TTF1 antibody.
(ABC, A x 250, B x 400).

A bronchioloalveolar carcinoma invading the overlying pleura exfoliates single and clustered malignant glandular cells in associated effusion. Tumor cells with “cell-embracing-cell” arrangement may be present. (Fig.1.14).

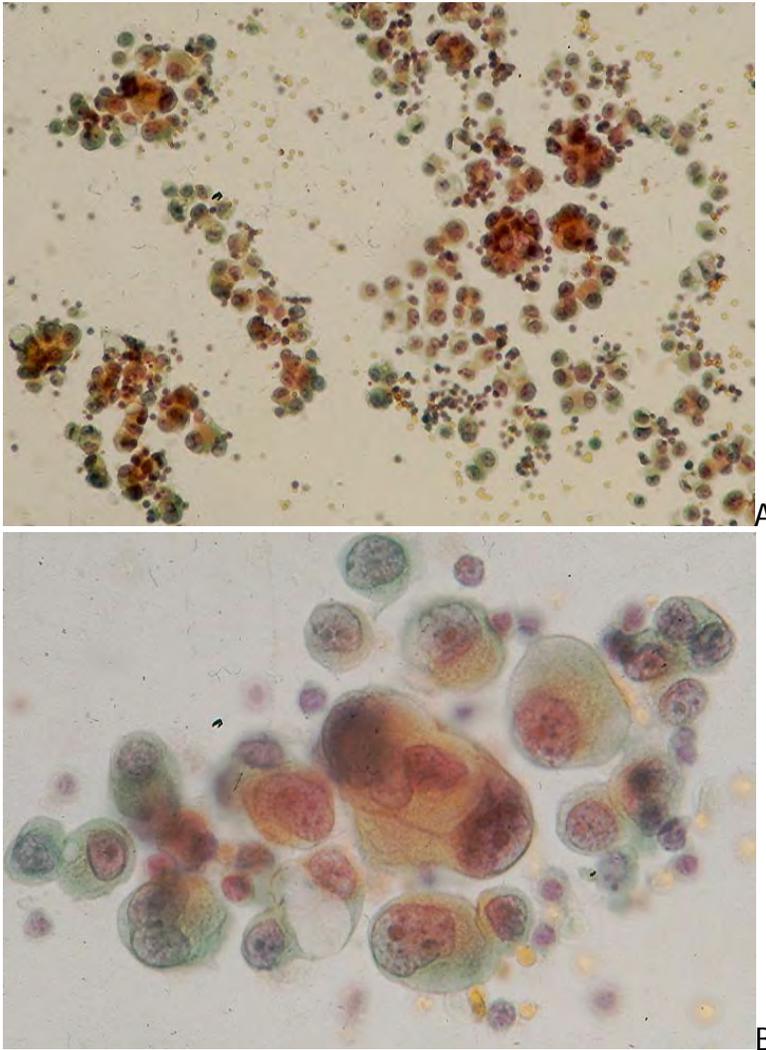

Fig.1.14. A bronchioloalveolar carcinoma showing single and clustered malignant glandular cells. A “cell-embracing-cell” arrangement is present in a small cell cluster at the center of figure B and 2 reactive mesothelial cells with a “window” between them cells are also seen. (Pap, A x 100; B x 400).

Bronchioloalveolar cell carcinoma arising from type II pneumocytes shows clustered pleomorphic malignant glandular cells with vacuolated cytoplasm that reacts negatively with mucicarmine and PAS reagent. Ultrastructural study of the effusion CB revealed

intracytoplasmic inclusions with "myelin figures" suggesting surfactant and confirming pneumocyte type II origin. (Fig. 11.15)

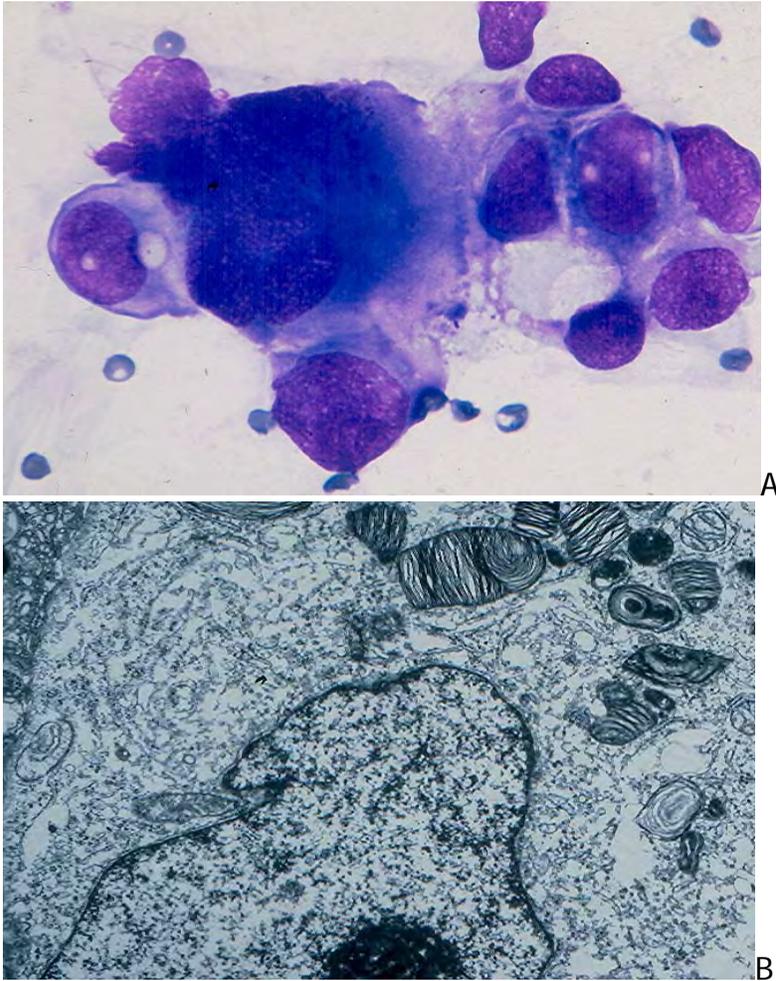

Fig.1.15: A: A cluster of pleomorphic malignant glandular cells in pleural effusion associated with a bronchioloalveolar cell carcinoma. (Diff-Quik, x 800).

B: Intracytoplasmic inclusion with "concentric myelin figure" suggesting that the tumor arises from pneumocytes type II. (Uranyl acetate and lead citrate stain, x 18,000).

2. *Large cell carcinoma* yields single, large pleomorphic cells. The tumor cells display enlarged nuclei, coarse chromatin and prominent single or multiple nucleoli. (Fig.1.16).

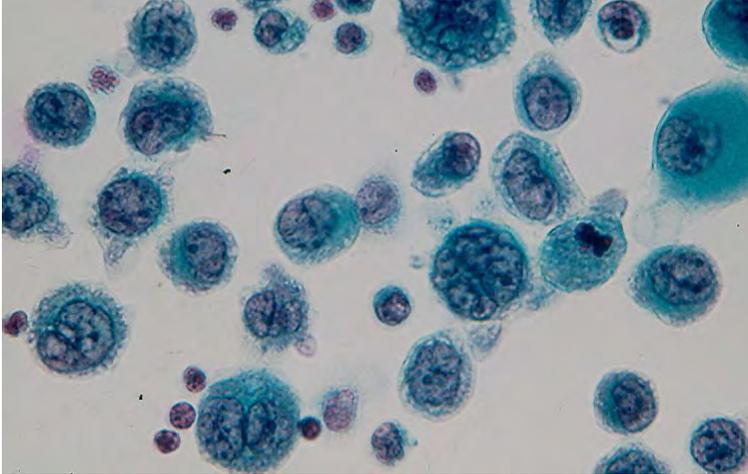

Fig.1.16. Isolated pleomorphic malignant cells with prominent nucleoli from a bronchogenic large cell carcinoma. (Pap, x 500).

3. *Squamous cell carcinoma* rarely exfoliates cells into an associated effusion. Cells from a well-differentiated or keratinizing tumor are usually present singly and in small clusters, and show a dense, "hard", eosinophilic cytoplasm suggesting keratin formation. (Fig. 1.17). Cells from a non-keratinizing or poorly differentiated tumor are commonly seen in large syncytial clusters and show a thin, ill-defined cytoplasm. However, single tumor cells with dense and thick or thin cytoplasm are noted in some cases of the poorly differentiated tumor. (Fig. 1.18 to 1.19). In other cases cells exfoliated from a poorly differentiated tumor shows cells indistinguishable from those of a lung adenocarcinoma. The neoplastic squamous cells are usually negative for CK7/CK20 and TTF1 and positive for CK5/6 and p63.

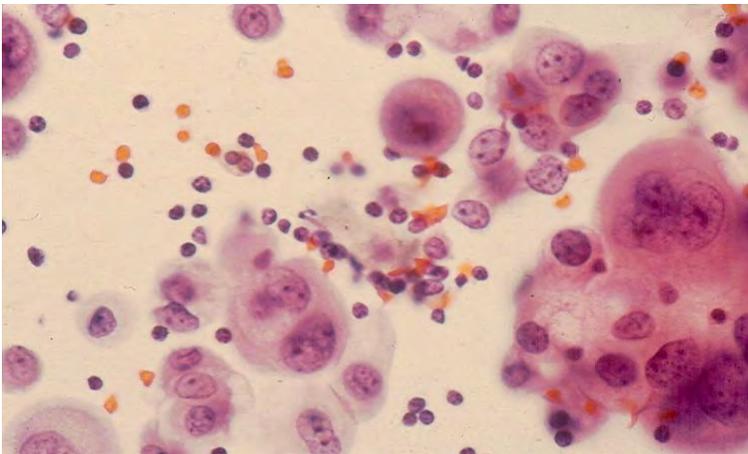

Fig.1.17. Pleural effusion from a metastatic well-differentiated squamous cell carcinoma showing single and clustered malignant squamous cells with keratinized cytoplasm. (Pap, x 500).

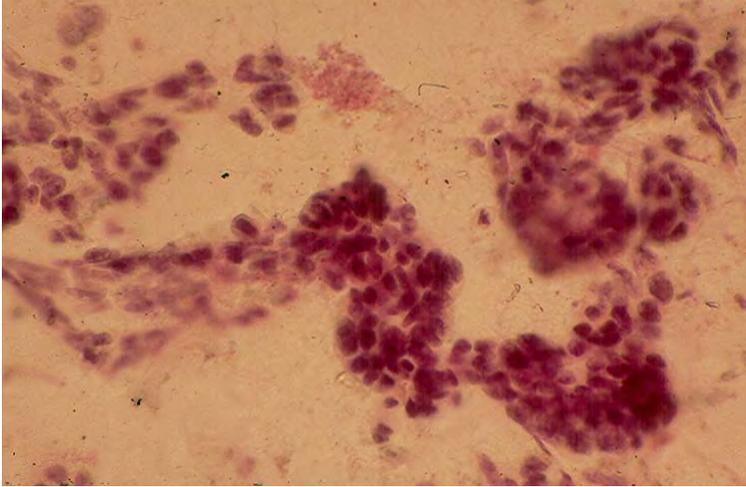

Fig.1.18. Pleural effusion from a metastatic poorly differentiated squamous cell carcinoma showing large irregular syncytial clusters of non-keratinizing cells. (Pap, x 250).

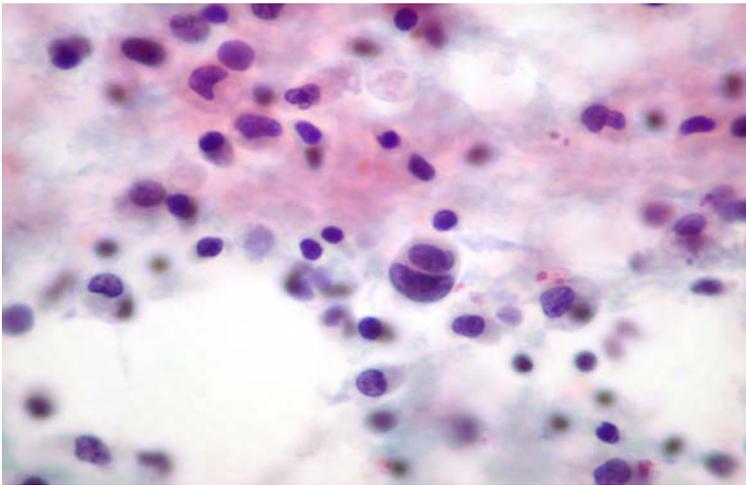

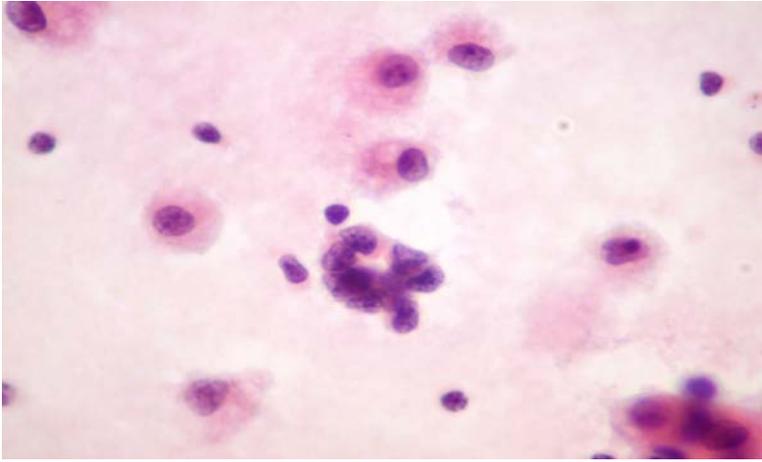

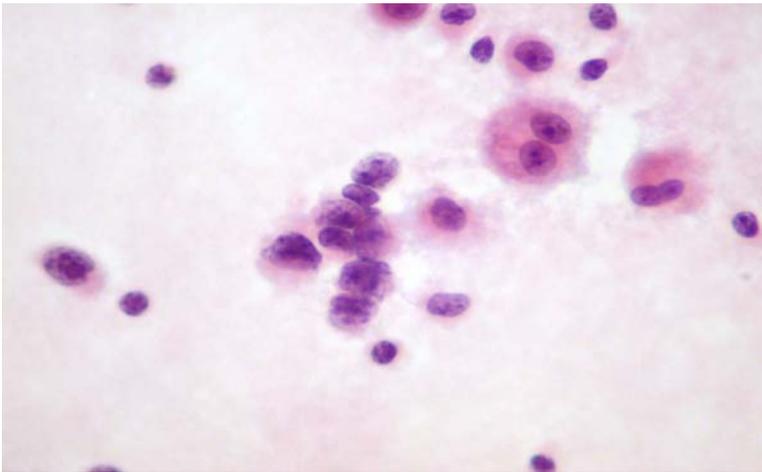

Fig.1.19. Pleural effusion from a metastatic poorly differentiated squamous cell carcinoma, small cell type, showing small tumor cells with hyperchromatic nuclei present singly and in small clusters. (Pap, x 400).

4. *Small cell carcinoma* (SCC) cells are small, cuboidal cells with scant cytoplasm and small, round nuclei with stippled (“salt and pepper”) chromatin and inconspicuous nucleoli. They are seen arranged in chains or clusters with nuclear molding. (Fig.1.20). In some cases the tumor cells are larger (SCC of intermediate cell type) and show conspicuous nucleoli, mimicking those of a non-small cell lung carcinoma. Rarely, cells from an SCC are present in large tridimensional clusters and loosely large aggregates, readily mistaken for those of a non-SCC. (Fig.1.21). Cells derived from a lung SCC commonly express neuroendocrine markers (neuron-specific enolase, chromogranin, synaptophysin, CD56) and TTF1.

A. abundant tumor cells singly and in large ball-like clusters.
B. Aggregated tumor cells with nuclear features of a small-cell lung cancer.
(Pap, A x 100, B x 500)

Breast Carcinoma

Metastatic breast carcinoma is responsible for about 25% of all malignant pleural effusions. Tumor cells from a *ductal carcinoma* are usually monomorphic, have irregular nuclei, multiple nucleoli and a non-vacuolated cytoplasm. They may resemble reactive and atypical mesothelial cells, and they are typically seen in abundant three-dimensional, large cell balls or morulae (>50 cells) and papillae. (Fig.1.22 and Fig. 1.23). In some cases the tumor cells are present singly. (Fig.1.24). These cells are CK7 positive, CK20 negative and often express ER, PR and Gross cystic disease fluid proteins.

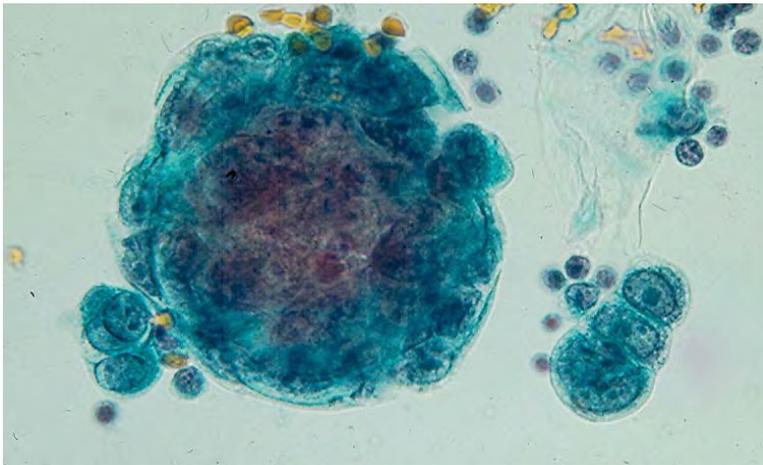

A

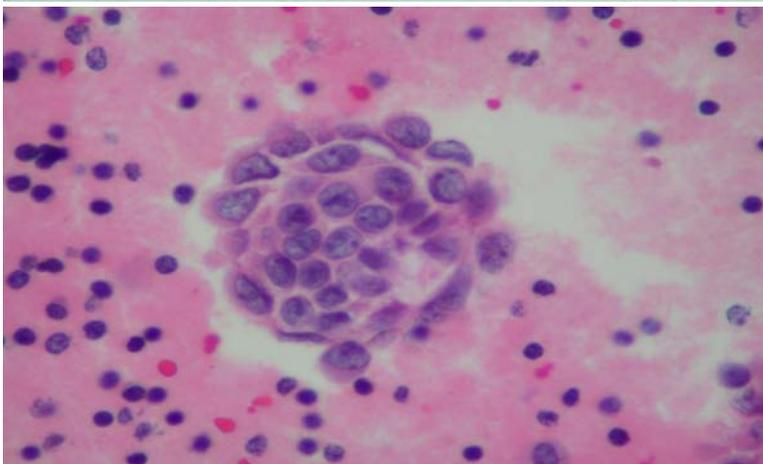

B

Fig.1.22. Pleural effusion from metastatic mammary duct carcinoma showing single and clustered monomorphic glandular cells. Tumor cells in linear arrangement are seen in A. (Pap, A, x 100; B, x 400).

A

B

Fig.1.23. Pleural effusion from a metastatic mammary duct carcinoma showing in A tumor cells with prominent nucleoli in a tight "ball-like" cluster and a linear row of three cells, and in B a tumor ball in a cell block section. (A. Pap, x 400, B. H&E, x400).

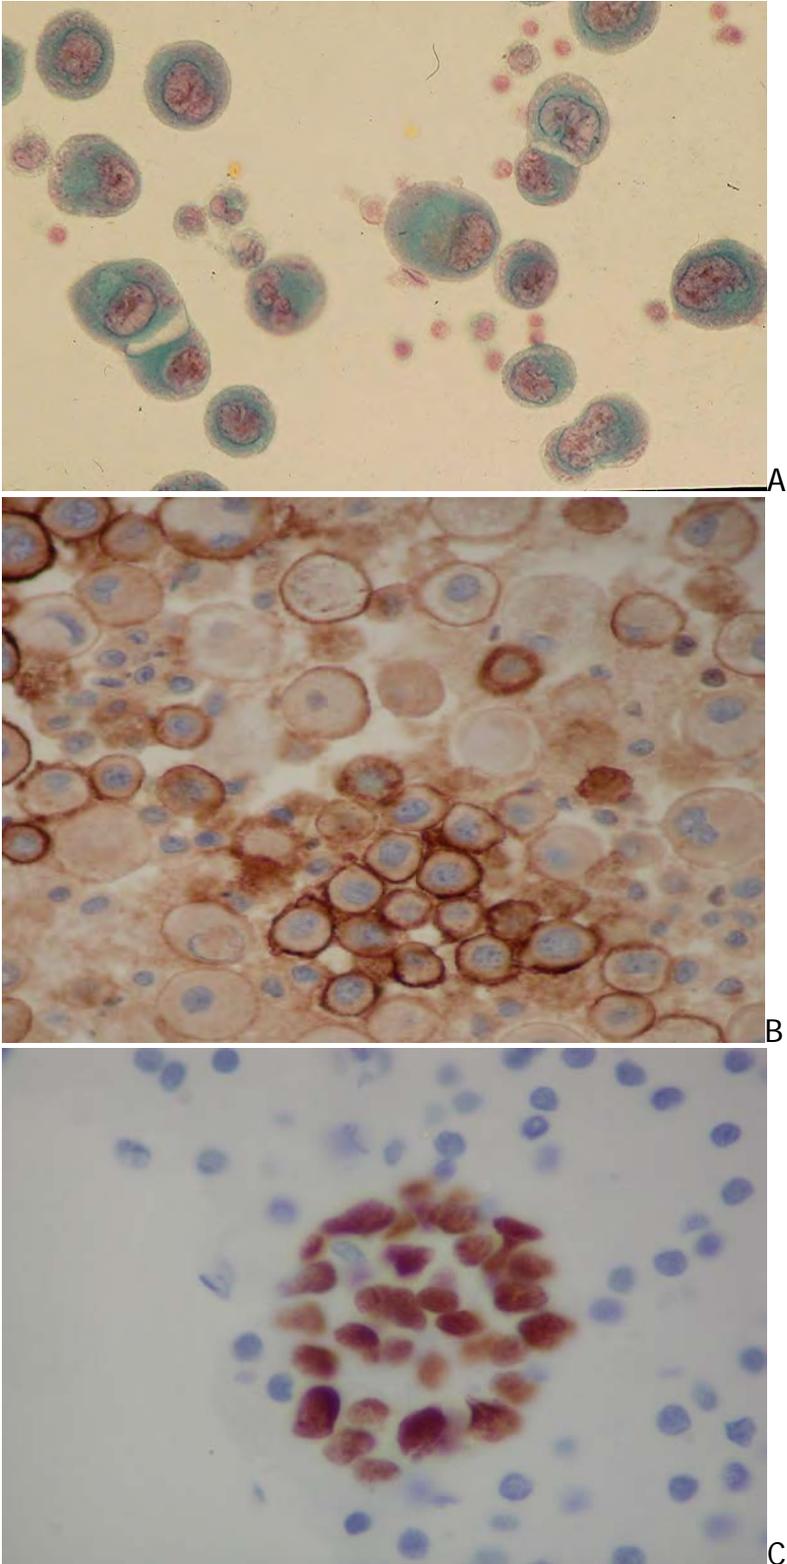

Fig.1.24. A: Large malignant glandular cells from a metastatic mammary duct carcinoma showing predominantly single cells with clear spaces or "windows" between adjacent tumor cells mimicking mesothelioma cells. (Pap, x 500).

B: IM stain on cell block section showing a membranous pattern with Ber-Ep4 antibody. (ABC, x 400).

C: positive reaction of tumor cell nuclei with Estrogen receptor antibody. (ABC, x500).

Metastatic *lobular carcinoma* of the breast usually shows small epithelial tumor cells with hyperchromatic nuclei that are present singly and in small chains. Single intracytoplasmic vacuoles containing mucinous droplets compressing tumor cell nuclei are seen. The cancer cells may be mistaken for cells derived from a metastatic signet-ring cell carcinoma. Their IM expressions are similar to those of a mammary ductal carcinoma.

Gastrointestinal carcinoma

Well- and moderately differentiated gastrointestinal *adenocarcinomas* usually show in effusions cohesive clusters of malignant glandular cells with intracytoplasmic vacuoles admixed with single tumor cells with similar features. A poorly differentiated adenocarcinoma yields large cells with vacuolated cytoplasm, pleomorphic nuclei and prominent nucleoli dispersed singly and in small clusters. (Fig.1.25).

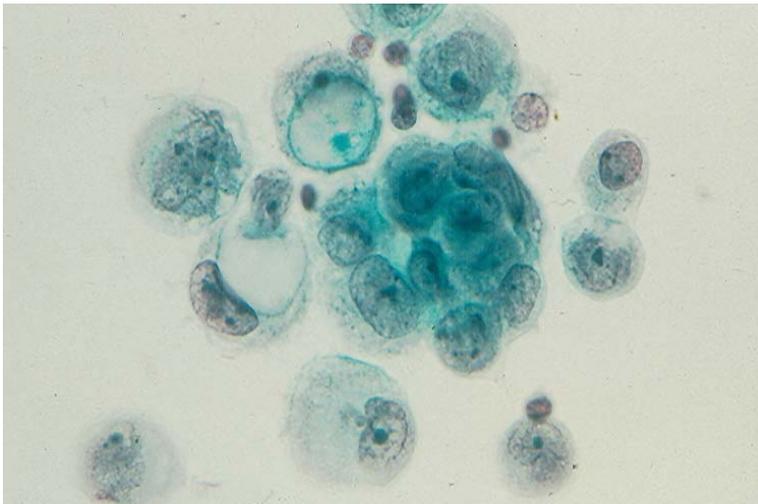

Fig.1.25. Poorly differentiated gastric adenocarcinoma in ascitic fluid showing single and clustered malignant glandular cells with prominent nucleoli. Some tumor cells have a large intracytoplasmic vacuole pushing their nuclei to the cell periphery, creating malignant signet-ring cells. (Pap, x500).

Single malignant glandular cells with signet-ring configuration are most commonly derived from a *diffuse carcinoma* or *signet-ring cell carcinoma* of the stomach. (Fig. 1.26).

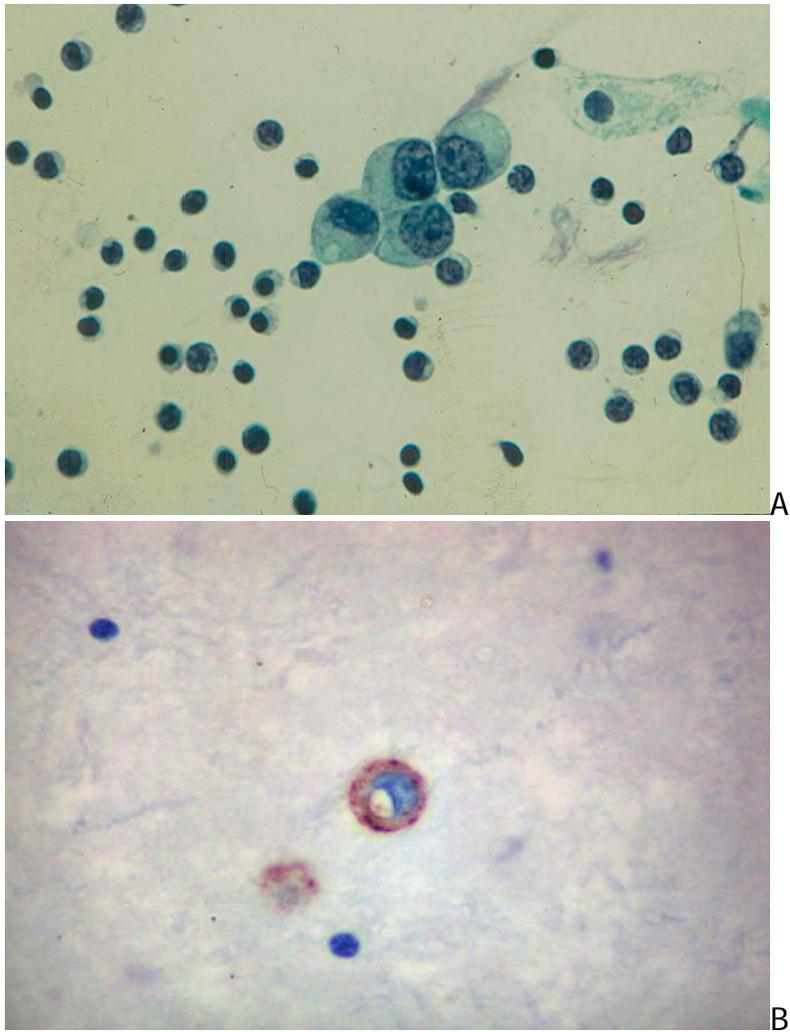

Fig.1.26. Diffuse gastric carcinoma:

A. A loose cluster of tumor cells with intracytoplasmic mucous vacuoles. (Pap, x 500).

B. Positive IM stain with CEA-monoclonal antibody of tumor cell cytoplasm. (ABC, x 400)

Adenocarcinoma of the appendix is the most common cause of mucinous ascitis (pseudomyxoma peritonei). The peritoneal effusion displays thick mucinous material, clustered malignant epithelial cells and proliferated capillary blood vessels. (Fig.1.27).

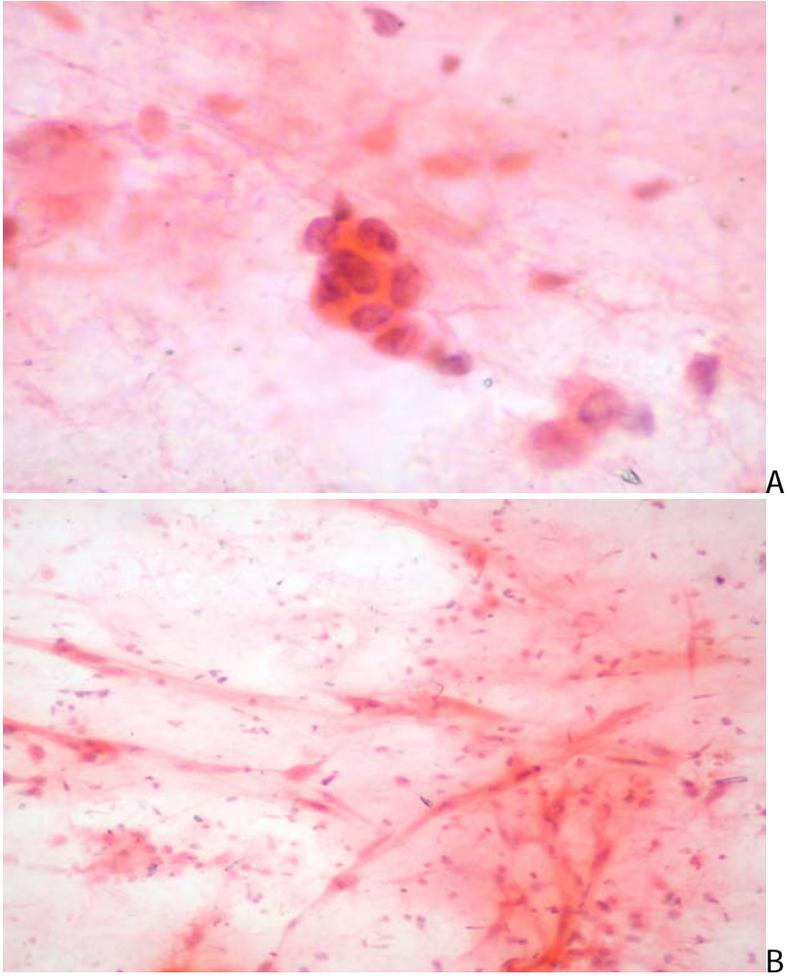

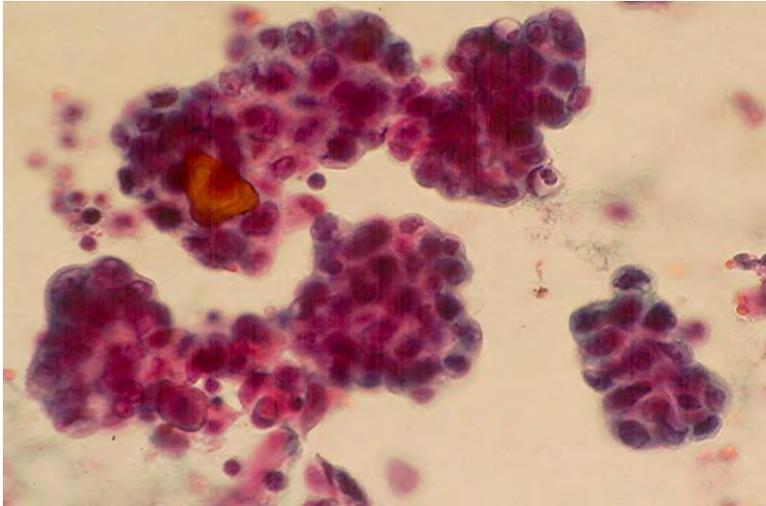

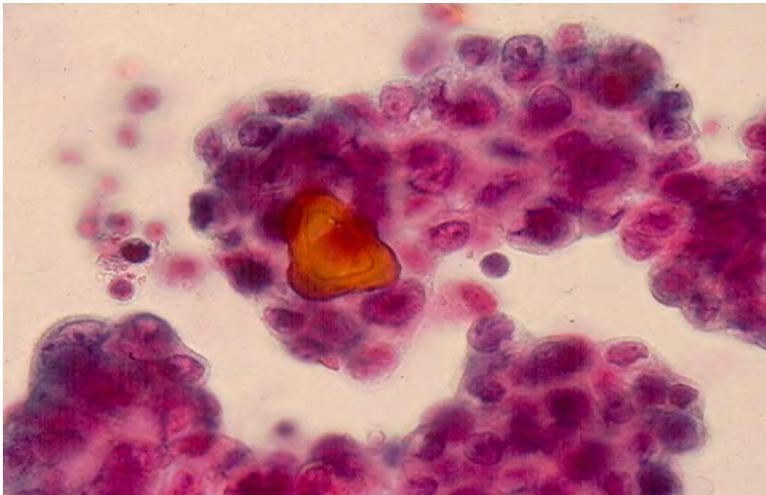

Fig.1.27. Pseudomyxoma peritonei secondary to an appendiceal adenocarcinoma:
A. A small cluster of malignant epithelial cells in a mucinous background.
B. Proliferated capillary blood vessels.
(Pap, A and B, x 400).

Ovarian carcinoma

Tumor cells derived from a *serous carcinoma* of the ovary are typically seen in papillary clusters, and psammoma bodies are often present. (Fig.1.28). It should be born in mind that cells from a papillary carcinoma of the lung and thyroid may also show psammoma bodies.

A

B

Fig.1.28 Metastatic ovarian serous carcinoma showing papillary clusters of tumor cells containing a laminated psammoma body. (Pap, A, x 100; B, x400)

A mucinous carcinoma shows clustered tumor cells with vacuolated cytoplasm in a background of mucin. (Fig.1.29). Cells derived from a serous ovarian carcinoma are Ber-Ep4, WT1 and CK7 positive and CK20 negative while those of a mucinous ovarian carcinoma are CK7 and CK20 positive and rarely express WT1.

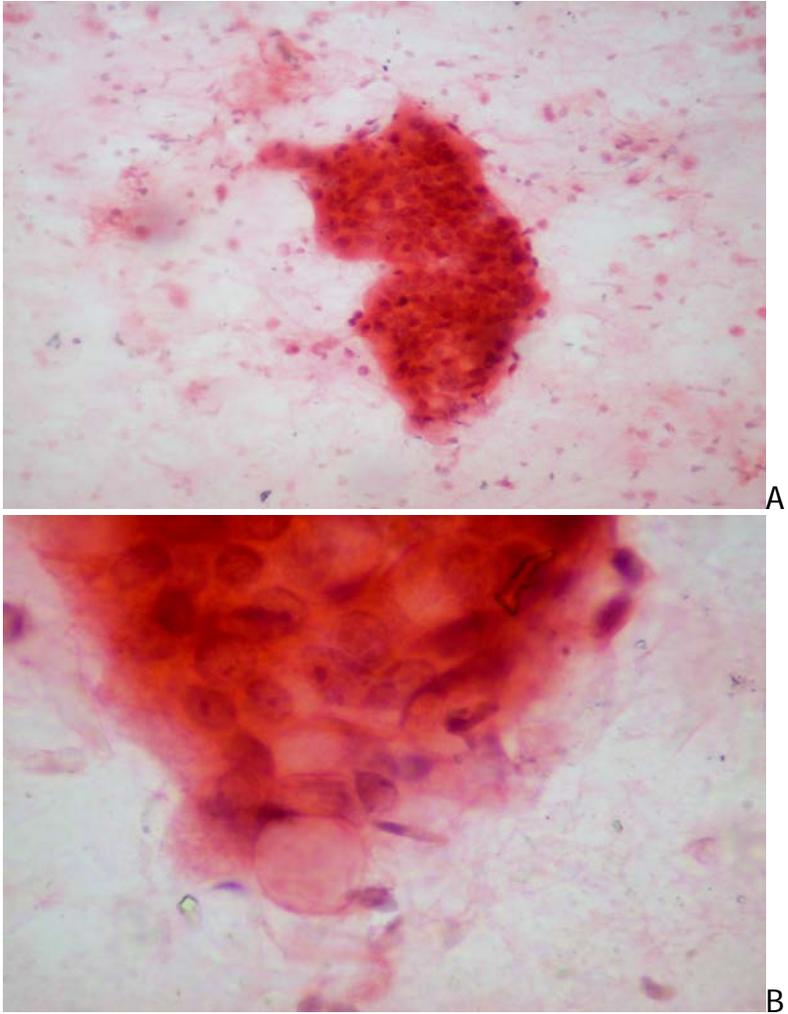

Fig.1.29. Mucinous ovarian carcinoma metastatic to the pericardium showing:
A. Large tridimensional clusters of tumor cells in a mucinous background.
B. Tumor cells with intracytoplasmic mucous are seen at higher magnification.
(Pap, A. x 100; B x 400).

Other Carcinomas

Urothelial carcinoma, high-grade of the urinary tract exfoliates its cells singly and in cohesive clusters. The tumor cells show granular, well-defined cytoplasm, oval nuclei, granular chromatin and prominent nucleoli. (Fig.1.30). These cells express CK7 and CK20, uroplakin, thrombomodulin and p63.

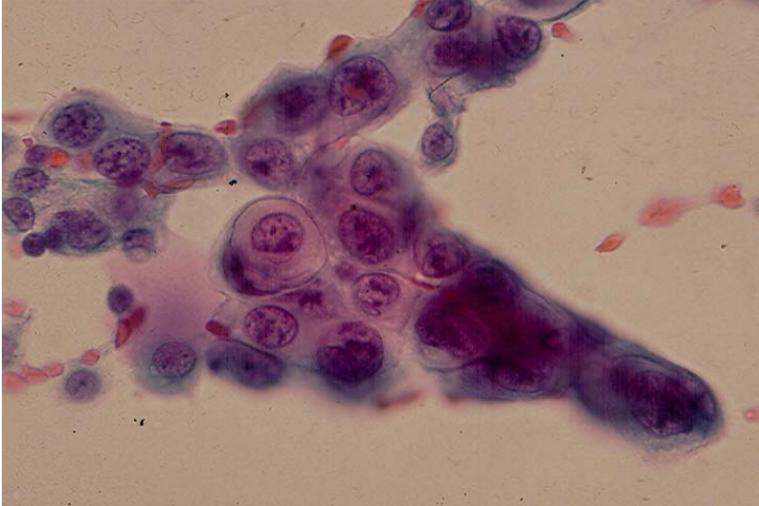

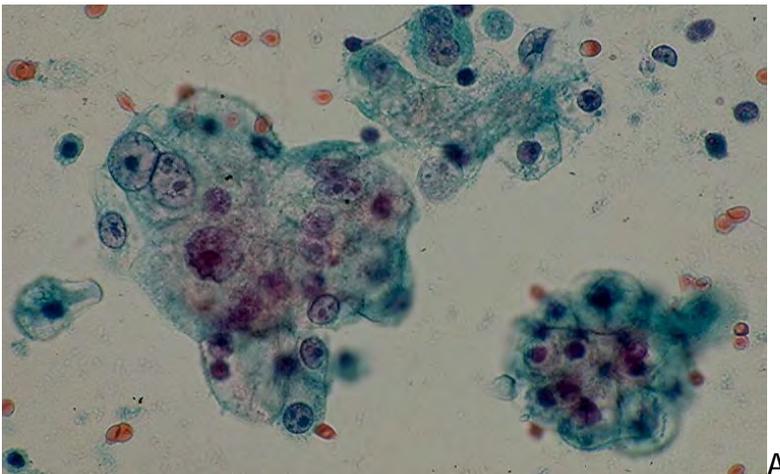

Fig.1.30 A cohesive cluster of malignant epithelial cells with thick, granular cytoplasm from a metastatic high-grade urothelial carcinoma. (Pap, x 500)

Hepatocellular Carcinoma exfoliates single or clustered large, polygonal malignant cells with abundant, granular cytoplasm and large, oval nuclei with macronucleoli. These cells may show intracytoplasmic bile pigment granules, intercellular bile plugs and intracytoplasmic globular inclusions. The tumor cell cytoplasm stains negatively with CK7/CK20 and positively with Hepar1 and alpha-fetoprotein antibodies.

Renal Cell Carcinoma of clear cell type yields cohesive tumor cell clusters with clear or granular cytoplasm and oval, large nuclei with prominent nucleoli. The tumor cells express pan-cytokeratin, EMA, vimentin, renal cell carcinoma antigen and PAX-2 but are CK7/CK20 negative. (Fig.1.31).

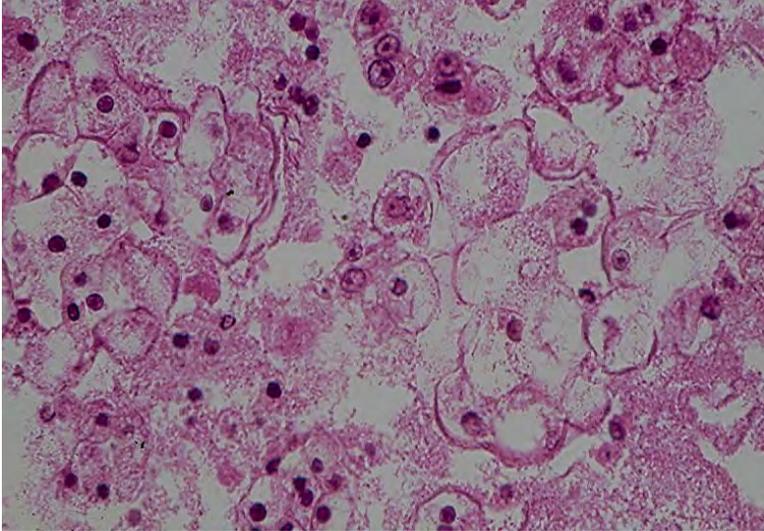

Fig.1.31 Metastatic renal cell carcinoma to the pleura showing in associated effusion clustered malignant cells with clear cytoplasm and prominent nucleoli. (A: Pap, x 500; B, cell block: HE, x 250).

Neuroendocrine Carcinoma may arise from the bronchial tree, pancreas, bowels and several other anatomic sites. It exfoliates medium-sized polygonal cells with oval nuclei with stipple chromatin, conspicuous nucleoli and granular cytoplasm. They are commonly present in groups and large clusters with moderate cohesiveness. Nuclear molding may be observed. The cell cytoplasm is CK7 positive, CK20 negative and expresses NSE, synaptophysin and chromogranin.

Germ Cell Neoplasms usually arise from the testicles in man and ovaries in woman. They are a group of tumors of different histologic types, and except for mature teratoma. (Fig.1.32). They are generally positive for CK7 and placental alkaline phosphatase and negative for CK20 and EMA. *Endodermal sinus tumor* (yolk sac tumor) cells show, in addition, a positive reaction with alpha-fetoprotein antibody. *Choriocarcinoma* cells express human chorionic gonadotrophin and CK7. *Embryonal carcinoma* cells express pancytokeratins, CD30 and OCT4. *Seminoma/dysgerminoma* cells are OCT4 positive and keratin negative.

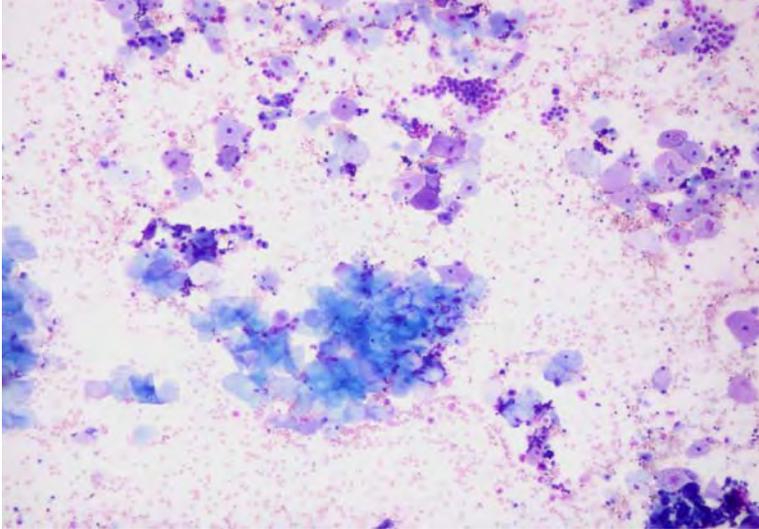

Fig. 1.32 Peritoneal fluid from a young woman with a ruptured ovarian dermoid cyst (mature teratoma) reveals fluid with superficial and anucleate squamous cells. Squamous cells, in small numbers, are usually represent a contaminant but can be tumor related. (Diff-Quik, x 100).

A metastatic dysgerminoma to the lung shows in pleural effusion single and loosely clustered large malignant cells with variable, defined cytoplasm and large, round or oval nuclei with prominent nucleoli. (Fig.1.33).

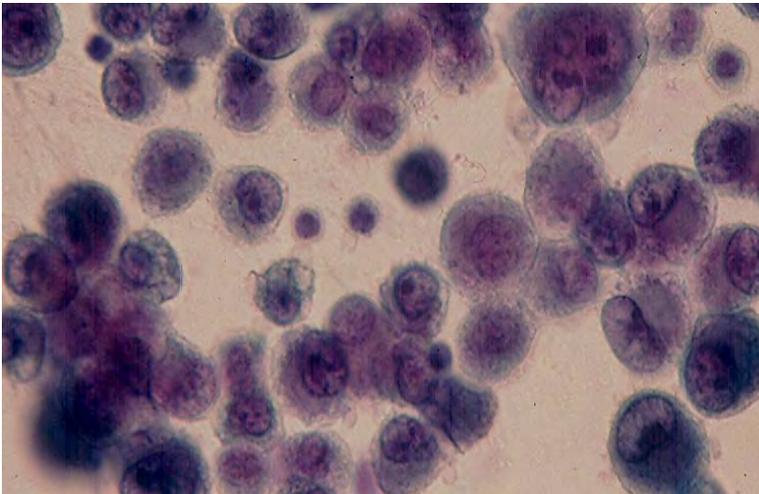

Fig.1.33 Dysgerminoma metastatic to the lung showing in pleural effusion single and loosely clustered malignant tumor cells with prominent nucleoli. (Pap, x 500).

Malignant Non-epithelial Tumors

Lymphoma and **Leukemia**. These tumors are the commonest non-epithelial malignant tumors associated with a positive effusion. **Hodgkin lymphoma**, depending on its

histologic variant, may exfoliate lymphocytes and eosinophils in addition to its diagnostic Reed-Sternberg cells. (Fig.1.34).

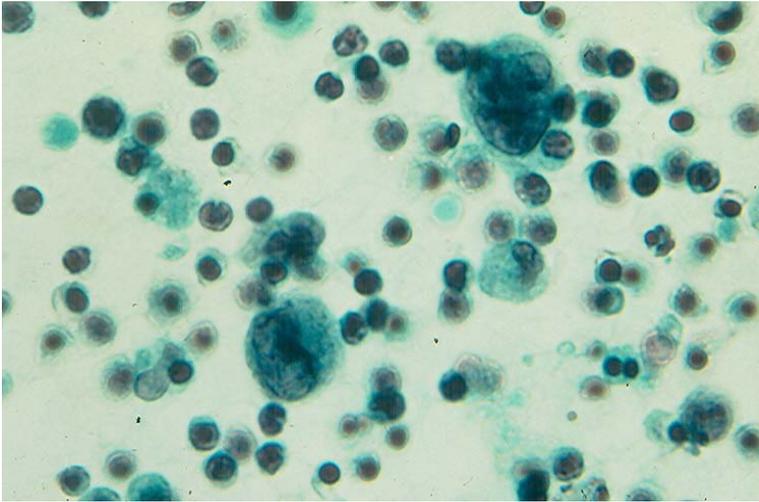

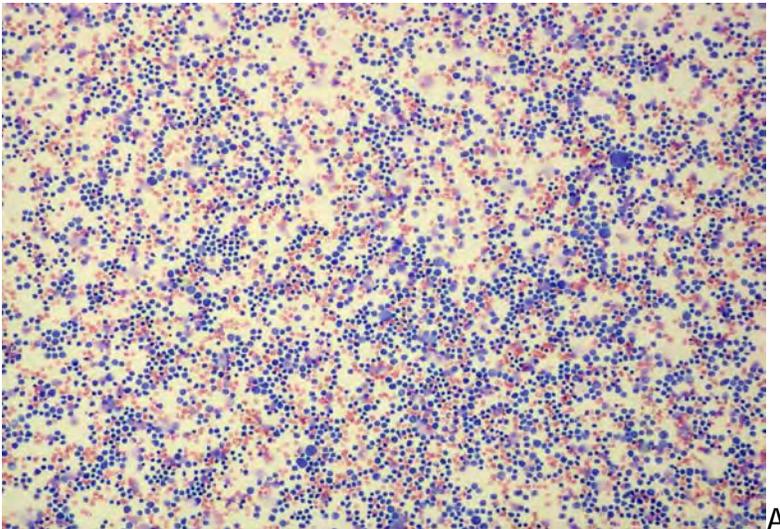

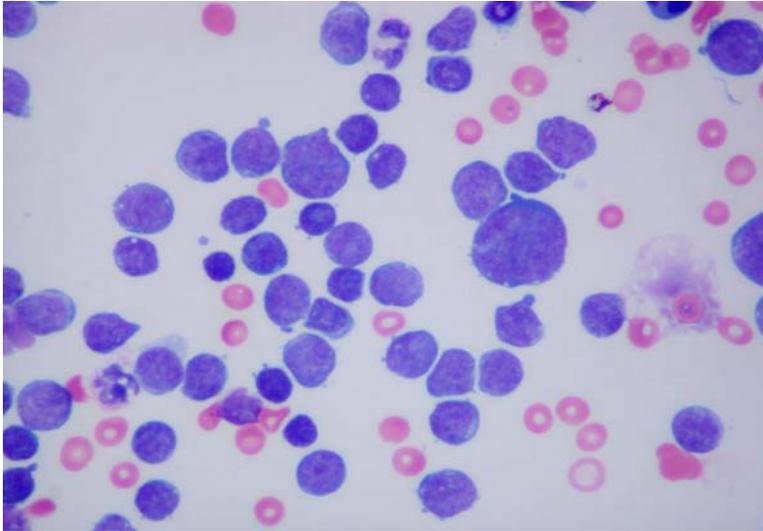

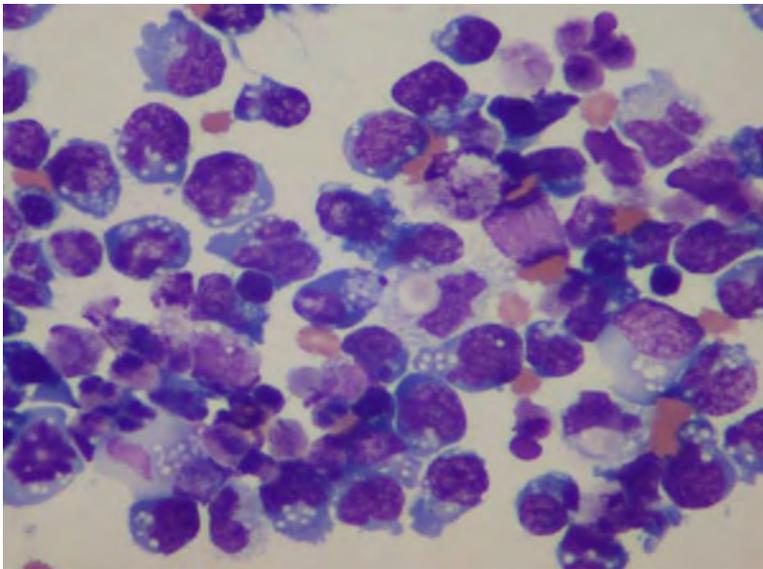

Fig.1.34 Hodgkin disease involving the pleura showing in associated effusion numerous benign lymphoid cells and 2 Reed-Sternberg cells. (Pap, x 500).

Non-Hodgkin lymphomas shed tumor cells varying from benign-appearing lymphoid cells similar to mature lymphocytes in small lymphocytic lymphoma/ chronic lymphocytic leukemia to atypical enlarged lymphoid cells with nuclear indentations and protrusions in higher grade lymphomas. (Fig.1.35). In acute leukemia blast cells may be present. Cells of a **chronic myelogenous leukemia** consist of mature and immature myelogenous cells without a "leukemic hiatus", as seen in an acute myelogenous leukemia.

B

C

Fig.1.35. Non-Hodgkin lymphoma:

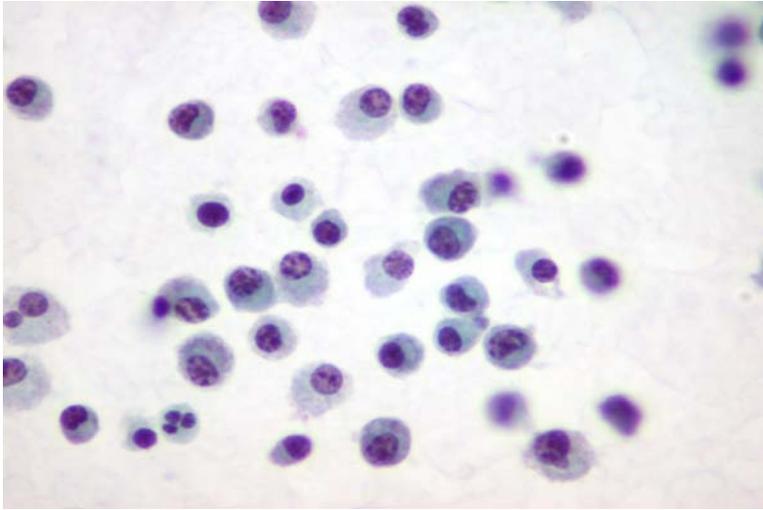

A. Effusion is usually highly cellular with dispersed single tumor cells.

B. Low-grade tumor showing cells with mildly nuclear atypia.

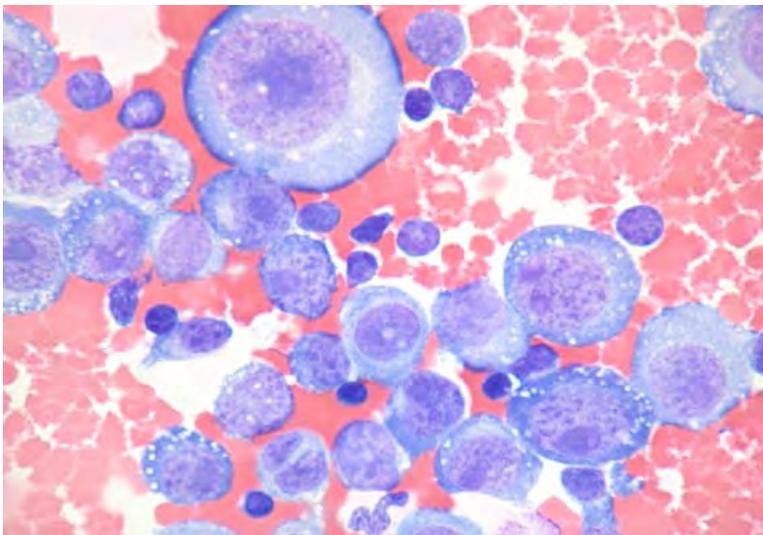

C. High-grade tumor showing large cells with pleomorphic nuclei and vacuolated cytoplasm.

(Diff-Quik, A, x 100; B and C, x 400).

Multiple myeloma involving the pleura shows single cancer cells with eccentrically located nuclei with cart-wheel chromatin clumping. (Fig.1.36).

A

B

Fig.1.36. A. Neoplastic plasma cells with eccentrically located nuclei. (Pap, x 400).
B. Neoplastic plasmablasts in a pleural fluid. (MGG x 500)

Melanoma cells may occur singly and in cohesive clusters. Intracytoplasmic melanin pigment granules, intranuclear cytoplasmic inclusions and macronucleoli are commonly present. (Fig.1.37). A positive cytoplasmic reaction with S-100 protein, HMB-45 or MART1 antibodies is diagnostic of the tumor.

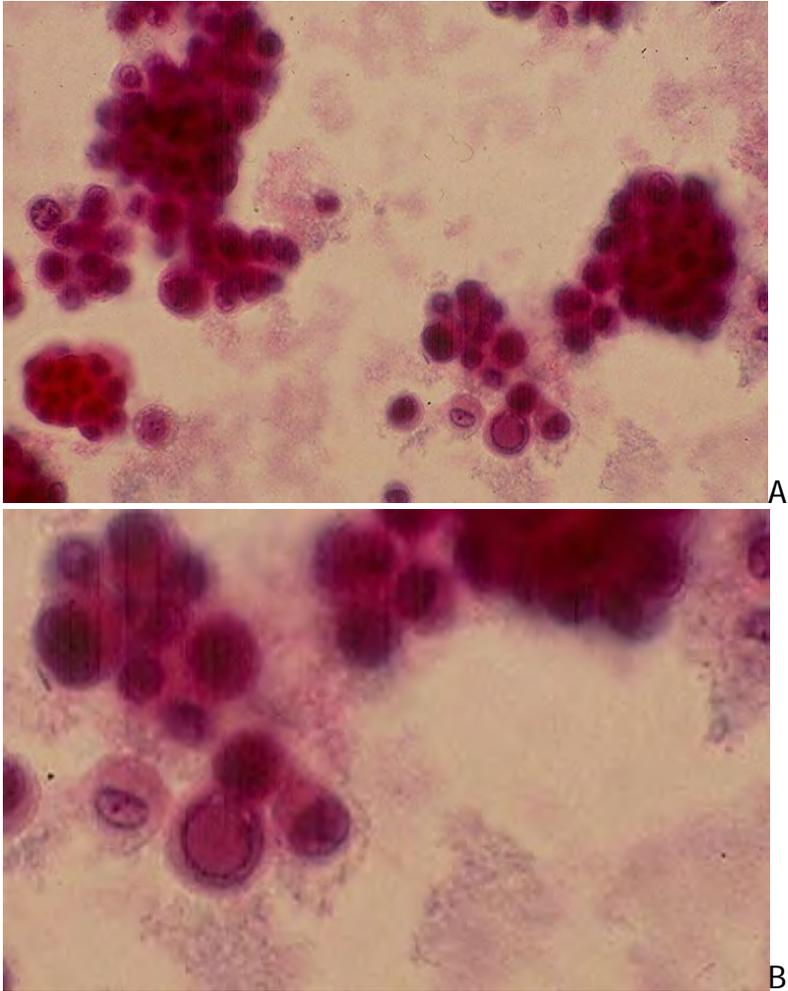

Fig.1.37. Pleural effusion from a cutaneous melanoma metastatic to the lung:
 A & B: single and clustered tumor cells showing a large intranuclear cytoplasmic inclusion. (Pap, A: x 200; B: x 500).

Bone and Soft Tissue Sarcomas show single and loosely clustered tumor cells. The tumor cells tend to have a round configuration and lose their original shapes in tissue sections. Typing of sarcoma cells is difficult without clinical data, cytochemical, IM, EM and cytogenetic studies.

Osteogenic sarcoma usually shows rounded large malignant cells with macronucleoli. Cells from a *chondrosarcoma* display abundant, well-defined cytoplasm and macronucleoli. (Fig.1.38). *Ewing sarcoma* yields small polygonal cells with oval nuclei and glycogen-rich cytoplasm singly and in rosettes. (Fig.1.39). The tumor cell cytoplasm stains positively with PAS and negatively with PAS with prior diastase digestion and reacts positively with CD99 antibody.

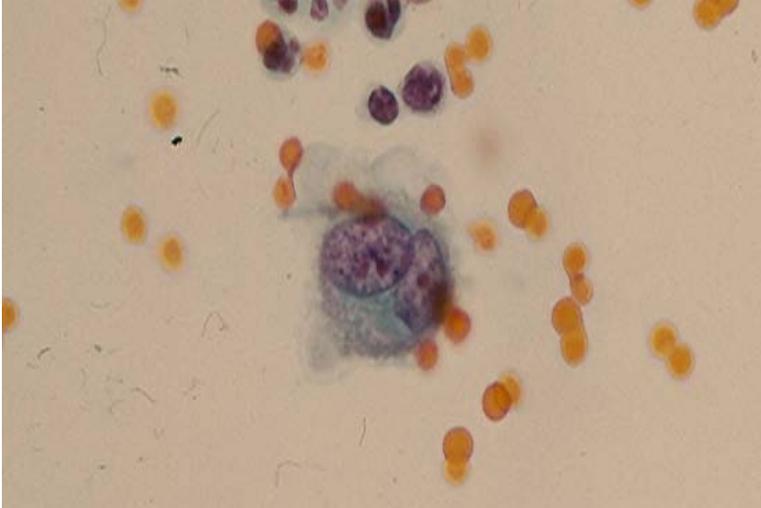

Fig.1.38. Pleural effusion from a metastatic chondrosarcoma showing single malignant cells with basophilic cytoplasm and double conspicuous nucleoli. (Pap, x 400)

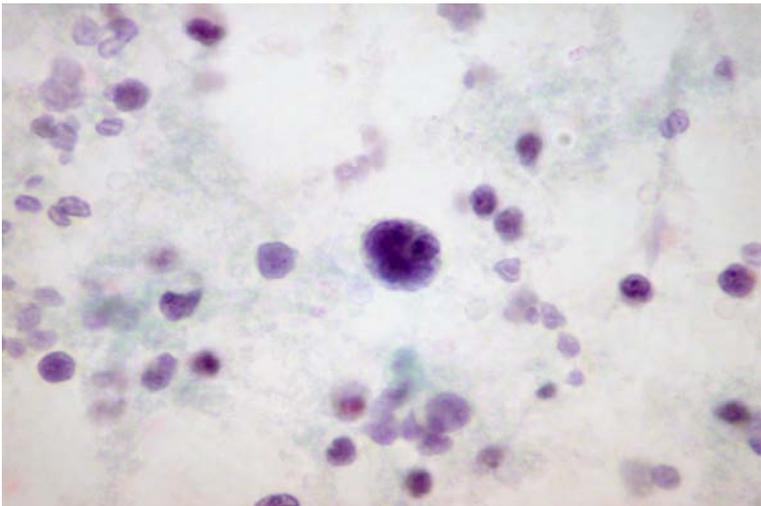

Fig.1.39 Metastatic Ewing sarcoma cells present singly and in a small rosette. (Pap, x 400).

Biphasic synovial sarcoma may show in associated effusions epithelial-like and spindle-shaped tumor cells in loose aggregates. (Fig.1.40). Epithelial-like tumor cells with focal gland-like arrangement may be seen, and a transition between these two types of cells may be observed. The tumor cells express cytokeratin and vimentin.

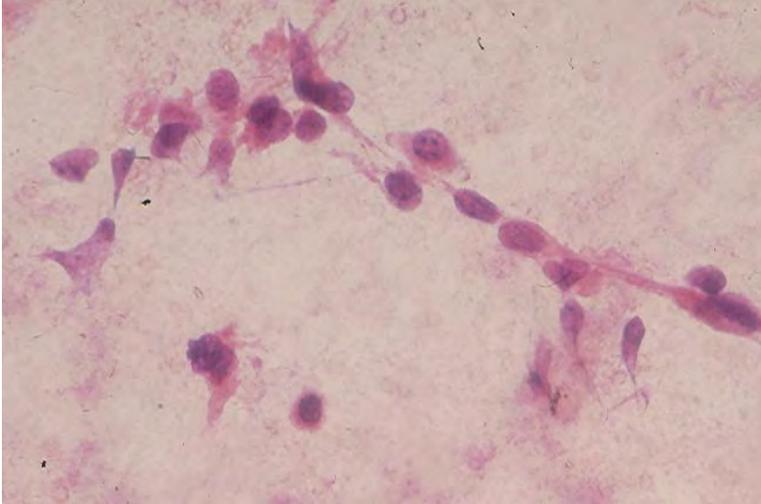

Fig.1.40. Spindle malignant cells with scant cytoplasm in pleural effusion associated with a metastatic synovial sarcoma to the lung. (Pap, x 400).

Leiomyosarcoma. A high-grade uterine leiomyosarcoma metastatic to the lung shows in associated effusion large single pleomorphic malignant cells with bizarre nuclei and dense, granular cytoplasm that stain positively with vimentin, desmin and smooth muscle cell antibodies. (Fig.1.41). The metastatic cancer cells are rounded up and show no resemblance to the cells in the primary tumor.

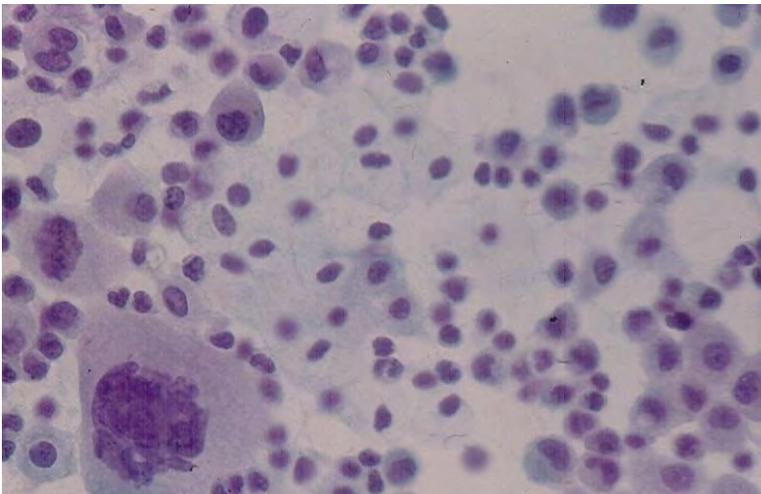

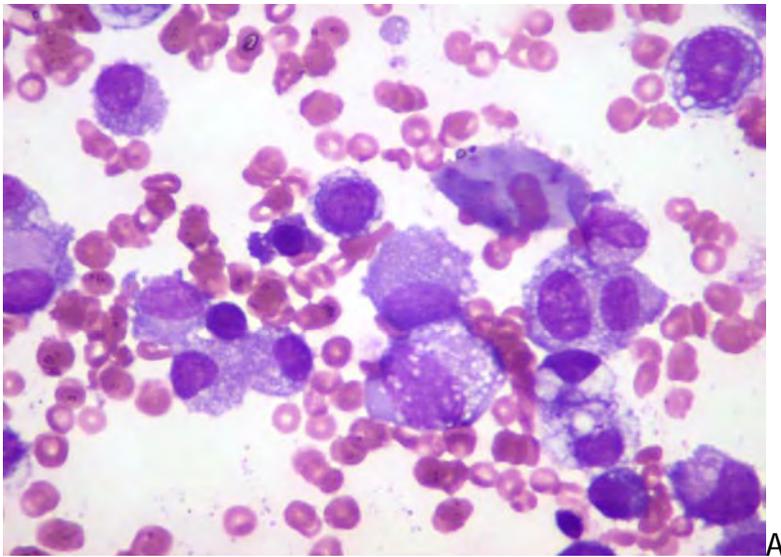

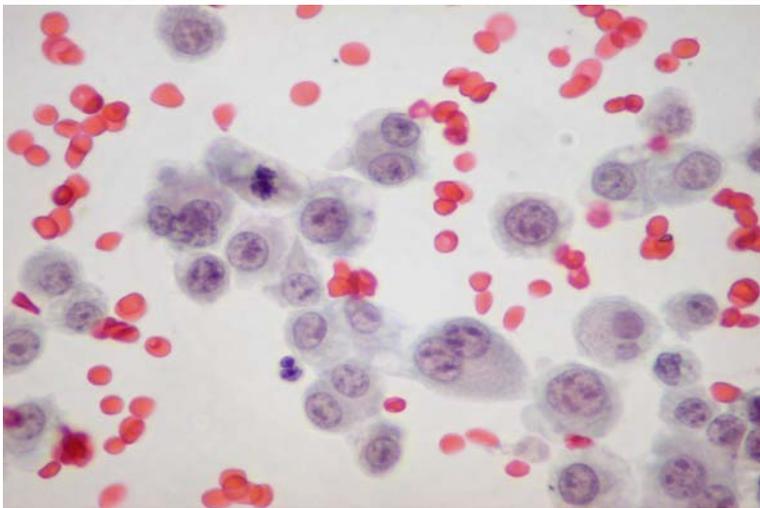

Fig.1. 41. Bizarre large malignant cells in a pleural effusion secondary to a uterine leiomyosarcoma metastatic to the lung. (Pap, x 400).

Melanoma of soft parts (clear cell sarcoma of soft parts) metastatic to the lung yields in associated pleural effusion single and loosely clustered polygonal cells with variably abundant cytoplasm. (Fig.1.42). The tumor cell cytoplasm expresses S-100 protein, Melan A and Mart 1.

A

B

Fig.1.42. Cells derived from a melanoma of soft parts present singly and in loose aggregates. (A, Diff-Quik and B, Pap x 400).

High-grade glioma metastatic to the lung yields in pleural effusion clusters of pleomorphic malignant cells that react positively with Glial fibrillary acidic protein antibody. (Fig.1.43).

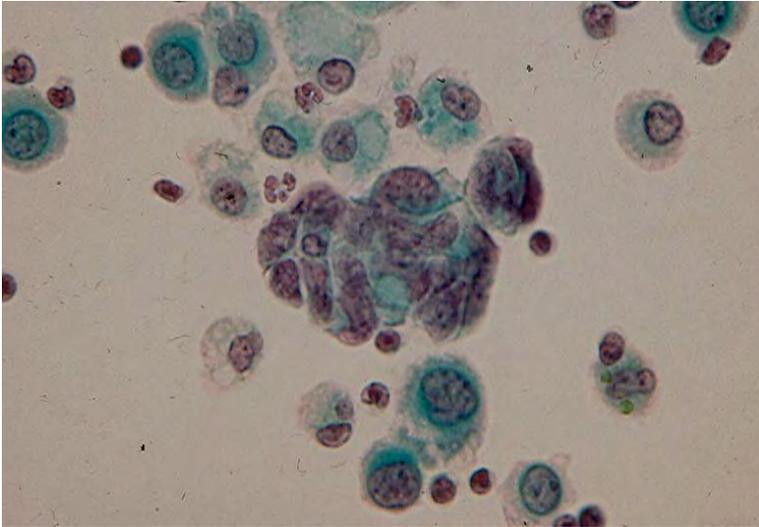

Fig.1.43 Clustered malignant cells from a metastatic high-grade glioma. (Pap, x 500).

MISCELLANEOUS SEROUS EFFUSIONS

1. *Pleural effusion caused by lung tuberculosis* shows an increased number of lymphoid cells with many displaying atypical nuclei. Epithelioid and multinucleated giant cells of Langhans are rarely observed. Mesothelial cells tend to be scanty. Culture is the best way to identify *Mycobacterium tuberculosis*.

2. **Eosinophil rich effusions**, usually pleural, are relatively common. (Fig.1.44). They result most often from air in the serosal cavity, as seen in pneumothorax, post surgery or repeated thoracentesis. They may also be related to infections (bacterial, viral, fungal, or parasitic), pulmonary infarcts, hypersensitivity reactions, or as part of a systemic eosinophilic disorder.

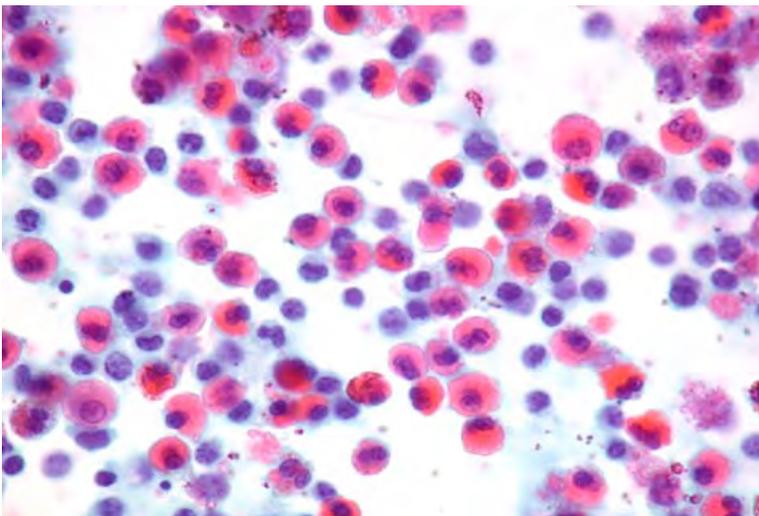

Fig.1. 44. Eosinophil-rich effusion. (Pap x 500)

3. Extramedullary hematopoiesis may be identified in effusions in patients with myelofibrosis. Immature blood cells and megakaryocytes are identified. (Fig.1.45).

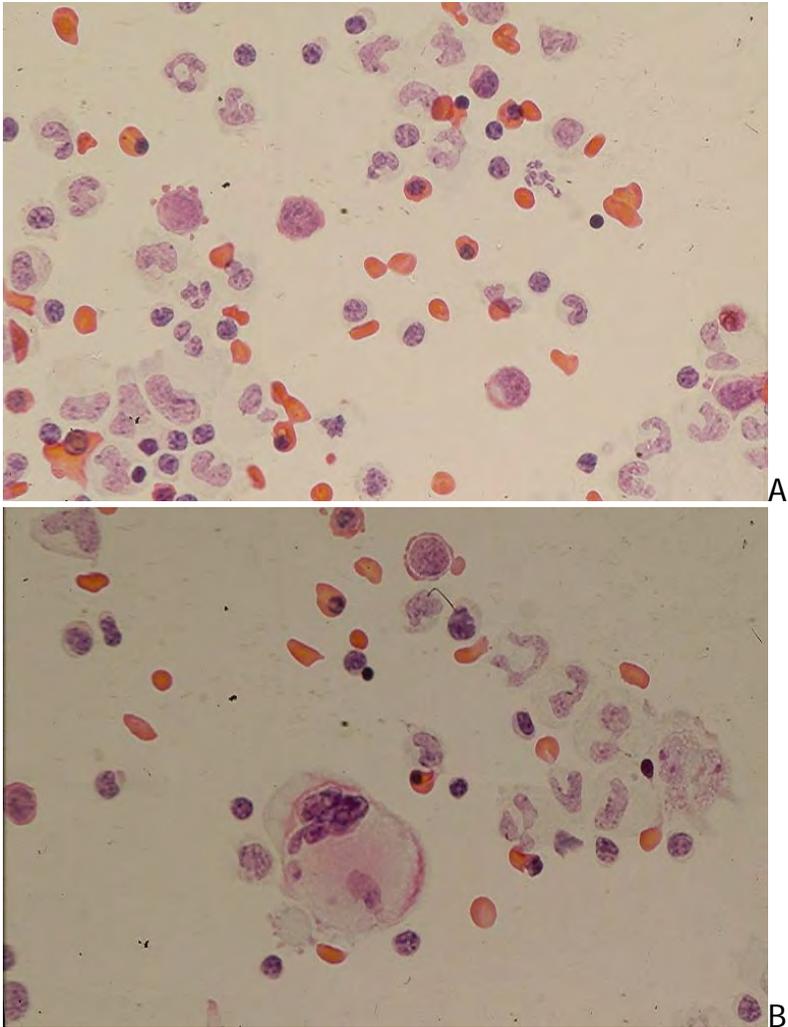

Fig.1.45. Benign bone marrow cells including a multinucleate megakaryocyte in ascites of a woman developing extramedullary hematopoiesis secondary to myelofibrosis with anemia. (Pap, A and B, x 400)

4. Collagen vascular diseases such as *Rheumatoid arthritis* and *Lupus erythematosus* may show in effusions some interesting cytologic findings:

- Histiocytes, neutrophils and granular necrotic debris may be seen in effusions of patients with rheumatoid arthritis.
- LE cells (polymorphonuclear leukocytes with large intracytoplasmic inclusions of degenerated and antinuclear antibody-coated nuclear material) may be observed in serous effusions of individuals with systemic lupus erythematosus. (Fig. 1.46). The LE cells may also be seen in patients with rheumatoid arthritis and in individuals taking drugs (procainamide, hydralazine) or having multiple myeloma and Hodgkin disease.

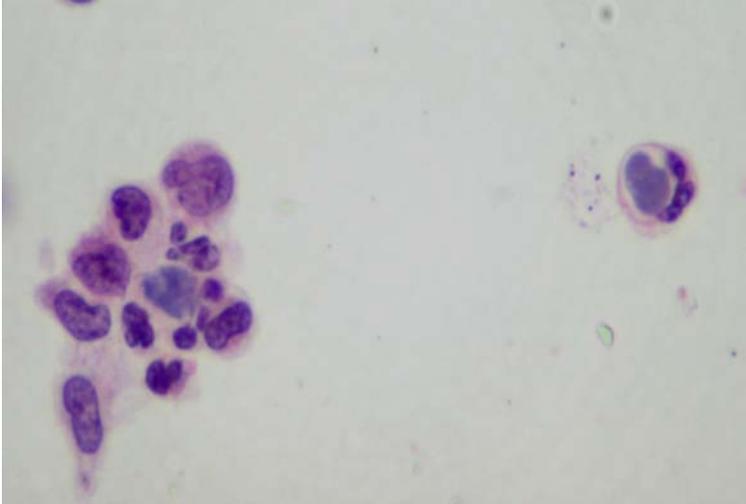

Fig. 1.46 LE cells in effusion of a patient with lupus erythematosus. (Pap, x 400).

4. Drug reaction-related effusions contain abundant eosinophils. Chemotherapy may produce atypical reactive mesothelial cells mimicking cancer cells.

5. Endometriosis may show in associated ascitis, morulae of endometrial epithelial cells and aggregates of hemosiderin laden macrophages.

6. Lung asbestosis may also associate with a nonspecific benign pleural transudate.

DIAGNOSTIC ACCURACY

Cytodiagnosis of malignant effusions is challenging and usually requires experience and immunohistochemistry. The diagnostic accuracy rate of malignant effusions is about 85% when multiple samples are evaluated. False-negative diagnostic rates vary widely among different reported series, and their main reasons consist of inadequate sampling, scantiness of cancer cells, faulty preparatory technique and erroneous interpretation. False-positive diagnostic rates up to 3% have been reported, and the most common error is the misinterpretation of reactive atypical mesothelial cells in long-standing benign effusions as cancer cells.

Comparative cytologic, IM and ultrastructural features of epithelial mesothelioma, reactive mesothelium and metastatic bronchogenic adenocarcinoma in serous effusions are tabulated in Table 1.1.

Table 1.1: Comparative Cytologic Manifestations of Reactive Mesothelium, Epithelial Mesothelioma and Bronchogenic Adenocarcinoma in Serous Effusions*

CELLULAR FEATURES	REACTIVE MESOTHELIUM	EPITHELIAL MESOTHELIOMA	BRONCHOGENIC ADENOCARCINOMA
Architecture:	-Singly, common -Monolayered sheets -Loose groups with "windows"	-Large cohesive clusters with lobulated borders -Small tight clusters with "windows" and "push-in" junctions	-Singly, rare -Tight multilayered, 3-dimensional clusters with smooth borders
Cells:

Peritoneal and Pelvic Washings

Diana N. Ionescu and Gia-Khanh Nguyen

Peritoneal and pelvic washings were first used by Keettel and Elkins in 1956 to detect early spreads of ovarian cancers that were not grossly identifiable on the peritoneal surface at laparotomy. This method of investigation has rapidly and increasingly gained a wide acceptance in evaluating cancers arising from the female genital tract and it is included in the FIGO staging systems for ovarian and endometrial cancers.

INDICATIONS AND GOALS

1. To assist in the initial staging of primary ovarian and endometrial cancers.
2. To exclude intraabdominal occult cancers in patients undergoing surgery for benign pelvic diseases.
3. To monitor the effectiveness of chemotherapy for advanced ovarian cancers (second-look laparotomy).
4. To assist in staging of some non-gynecologic abdominal cancers (gastric and pancreas)

COLLECTION AND PREPARATION OF CELL SAMPLES

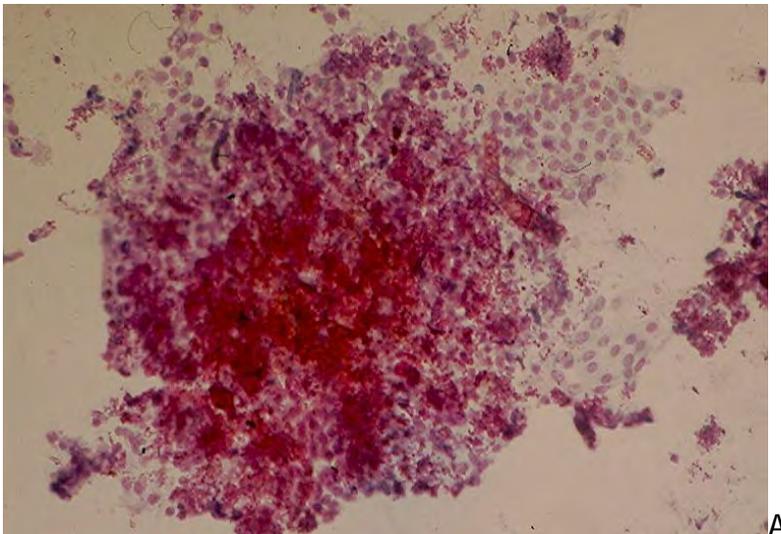

Any ascitic fluid present at laparotomy is collected and submitted as a separated sample for cytologic evaluation. A syringe with a long rubber catheter is used to instill 50 - 200 mL of sterile normal saline in 4 following anatomic sites: the inferior aspect of the diaphragm, right and left paracolic gutters and pelvic cavity. One option is to aspirate each of these sites and submit separate samples for cytologic evaluation. However, submitting a single sample specimen combining samples from all 4 sites has no inferior diagnostic value. Usually an equal volume of 50% ethanol is added to each cell sample to preserve cell morphology. As peritoneal washing (PW) specimens are usually heavily contaminated with blood that may obscure diagnostic cells, hemolysis of bloody specimens is necessary. Adding ethanol to PW samples has the advantage of destroying most red blood cells. Ficoll-Hypaque solution may be also used to separate red blood cells from nucleated cells.

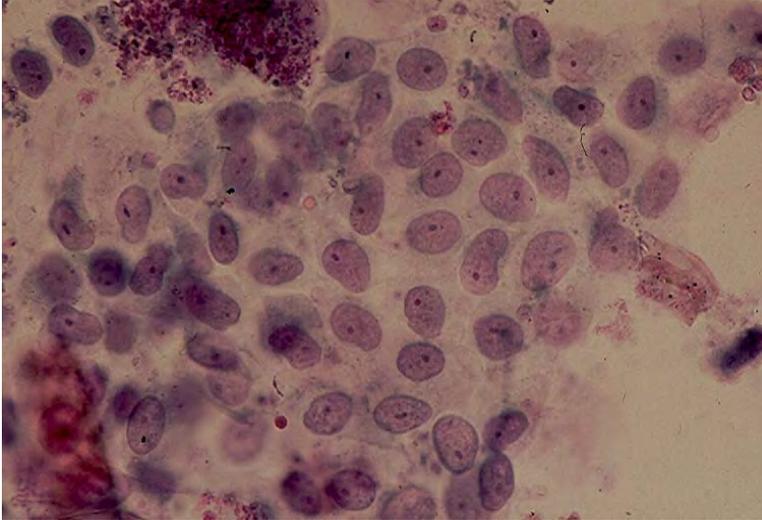

The fluid sample is then thoroughly mixed and a 100 mL aliquot is centrifuged at 1800 rpm for 10 min. The supernatant is discarded and the sediment is used to prepare 2-4 direct smears. It may be re-suspended in an appropriate amount of normal saline for cytopspin preparation. If the smears/preparations obtained are bloody they may be fixed in Carnoy solution for 3-5 min to lyse red blood cells. The remaining sediment, if present, is fixed in formalin for preparation of a cell block (CB) that may be used for IM staining, if necessary. The cell preparations/smears obtained are fixed in 95% ethanol and stained by the Papanicolaou method. CB sections are stained with hematoxylin and eosin.

CYTOLOGIC FINDINGS

1. Normal Peritoneal Washing

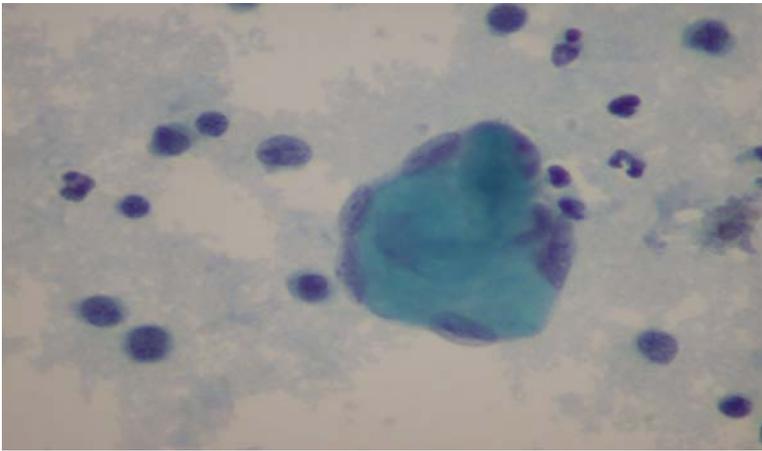

A PW cell sample from a healthy woman is usually cellular and contains large sheets of mesothelial cells that are forcibly exfoliated by washing. Single and clustered histiocytes are commonly present as well as polymorphonuclear leukocytes from the contaminated blood. Minute fragments of benign adipose tissue and skeletal muscle from the abdominal wall incision are also observed, mainly in PW cell blocks. The sheets of mesothelial cells are large and usually folded. These cell sheets consist of cohesive polygonal mesothelial cells with oval nuclei, thin and regular nuclear contours, fine chromatin and small nucleoli. Nuclear grooves are seen in many cells and focal nuclear crowding may also be observed. (Fig.2.1). On rare occasions papillary clusters of benign mesothelial cells containing psammoma bodies and masses of collagen surrounded by mesothelial cells ("collagen balls") may be seen. (Fig.2.2).

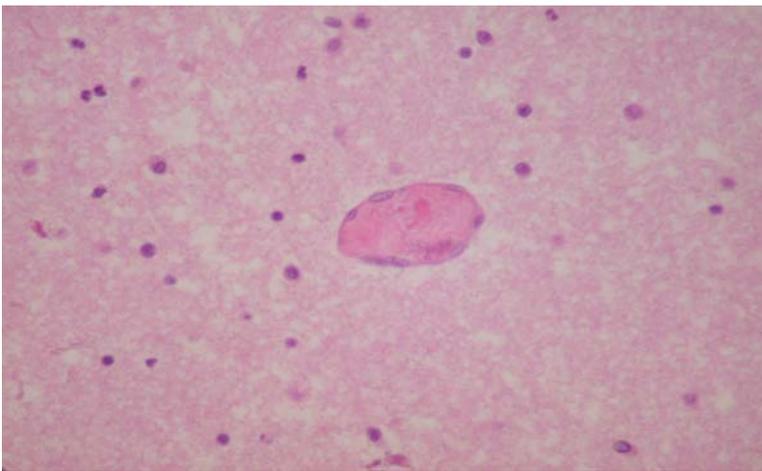

B

Fig.2.1. A large and irregular sheet of mesothelial cells forcibly exfoliated by peritoneal jet washing showing evenly spaced mesothelial cells that have ill-defined cytoplasm, oval or bean-shaped nuclei, small conspicuous nucleoli. (Pap: A, x 100; B, x 500).

A

B

Fig.2.2. "Collagene ball" in peritoneal washing cell film (A) and in cell block (B). (Pap, A x 400; HE, B x 200).

2. Gynecologic Malignant Tumors

Ovarian cancer. Ovarian carcinoma is a common neoplasm in women over 65 years of age. Most women with ovarian cancer are diagnosed at stage III or IV. Evaluation of PW is not required for advanced ovarian cancer but is important for staging stage I or II tumors. A positive PW in these two situations will change the tumor stages to IC and IIC, respectively. With the exception of serous borderline tumors, patients with stages IC and IIC ovarian carcinomas receive postoperative chemotherapy to delay recurrences. Presently, there is no convincing evidence that a positive PW predict a poor outcome, independent of other prognostic factors.

Serous Carcinoma is the commonest histologic type of ovarian cancers and the one that is often associated with a positive PW. Depending on its histologic grade the cytologic findings are different. A low-grade serous carcinoma will yield fairly monomorphic, small tumor cells organized predominantly in large tridimensional clusters. (Fig.2.3).

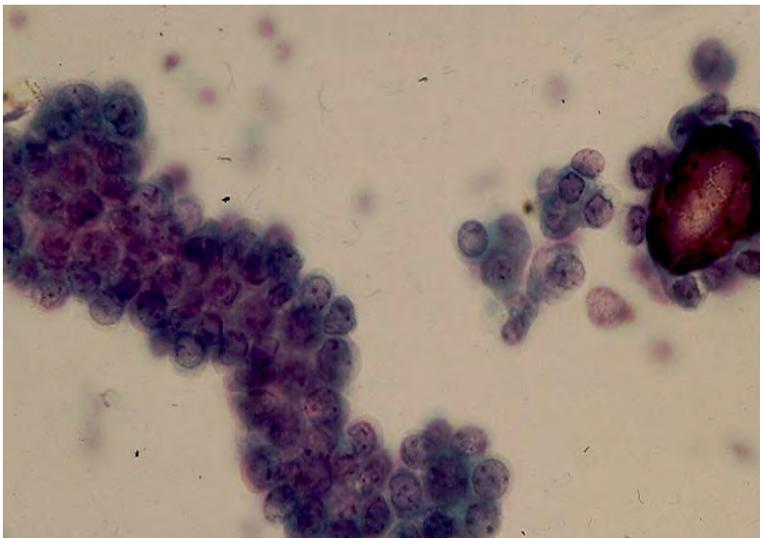

Fig. 2.3. Low-grade malignant epithelial cells attached to one psammoma body in PW of a woman with an ovarian low-grade serous carcinoma. (Pap, x 400).

A high-grade tumor is characterized by single and clustered pleomorphic malignant cells. (Fig. 2.4). Single and loosely clustered tumor cells with some cells showing vacuolated cytoplasm are seen. Psammoma bodies are often present within tumor cell clusters from low- as well as high-grade tumors.

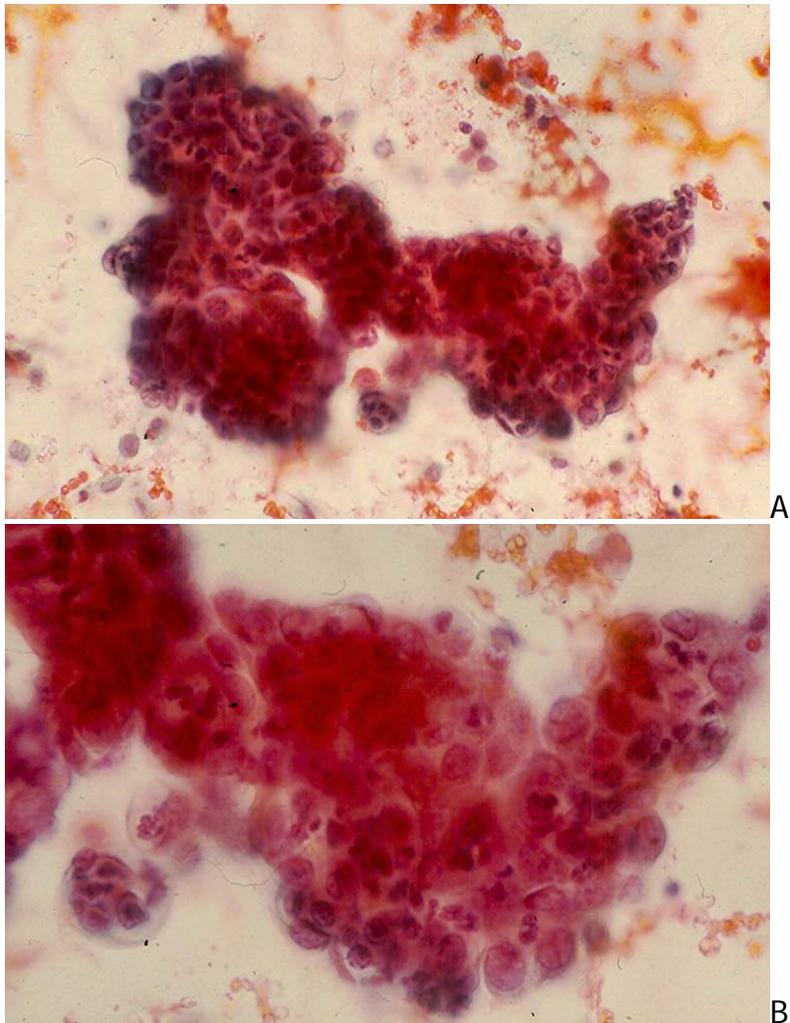

Fig. 2.4. High-grade ovarian serous carcinoma showing a thick irregular cluster of pleomorphic malignant epithelial cells with prominent nucleoli. (Pap: A, x 100; B, x 400).

Serous Borderline Tumor (also known as Serous tumor of low-malignant potential) is a low-grade neoplasm with significantly better prognosis than an ovarian low-grade serous carcinoma. The cytologic manifestations of a serous borderline ovarian tumor are similar to those of a low-grade serous carcinoma. A serous borderline tumor is distinguished histologically from a low-grade serous carcinoma by the absence of stromal invasion in the former. This important finding is readily identified by extensive sampling and histologic evaluation of the resected tumor.

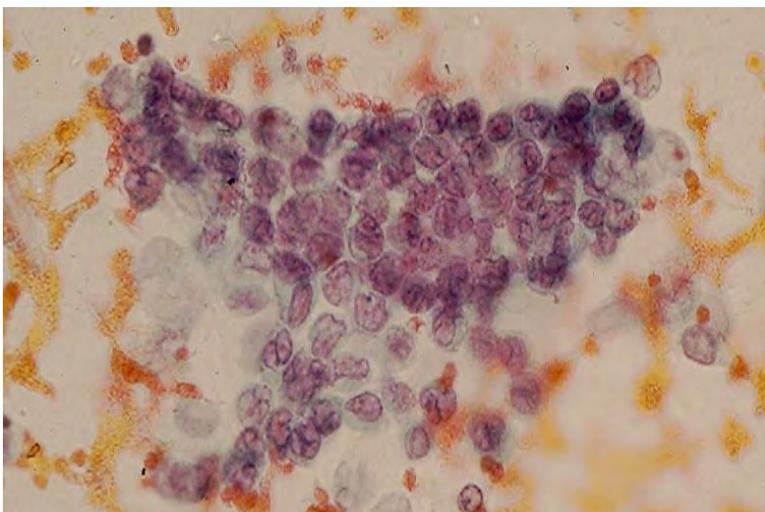

Mucinous Carcinoma of the ovary is less common than serous carcinoma and accounts for about 10-15% of all ovarian tumors. The majority of ovarian mucinous tumors are benign (75%) while 10% are borderlines and 15% are carcinomas. Most ovarian mucinous tumors are of intestinal type (85%) and present as unilateral tumors. The other histologic subtype, endocervical-like mucinous carcinomas are bilateral in up to 40% of cases. Regardless of their subtypes, these ovarian tumors yield in PW malignant

cells with large cytoplasmic vacuoles arranged in loose clusters and in linear arrangements or cell strips or singly.

Other ovarian cancers such as *Germ cell* and *sex-cord tumors* rarely involve the peritoneum or omentum.

Endometrial Cancer is the most common gynecologic malignancy and accounts for about 6% of all cancers in women. According to the old FIGO staging system for endometrial cancer a positive PW constitutes one of the criteria for stage IIIA. Recently, the revised FIGO staging system for endometrial states, with regards to stages IIIA and IIIB, that “positive cytology has to be reported separately without changing the stages”. However, a positive PW in this situation does not necessary indicate a poor prognosis, as endometrial cancer cells may spread onto peritoneal surface by transtubal retrograde dissemination. This may be facilitated by a prior endometrial biopsy and curettage, by a preoperative intracavitary placement of radium implants or hysteroscopy. Patients with endometrial cancer and positive PW usually have a high-grade tumor with deeper myometrial invasion and lymph node metastasis.

Endometrioid adenocarcinoma is the commonest histologic type of endometrial carcinomas. *Papillary serous* and *Clear cell carcinomas* and *Malignant mixed mullerian tumor* (MMMT) are rare neoplasms. When these tumors involve the peritoneum or omentum malignant cells may be detected in PWs. A low-grade endometrioid carcinoma is characterized by single and clustered small cuboidal malignant epithelial cells with scant cytoplasm, enlarged but monomorphic nuclei, coarse chromatin and conspicuous nucleoli. (Fig. 2.5). A high-grade tumor yields more pleomorphic malignant cells that may be present in loose aggregates or clusters. A papillary serous tumor is characterized by clustered small cuboidal cells with scant cytoplasm and enlarged hyperchromatic nuclei with inconspicuous nucleoli. A clear cell carcinoma shows single and clustered pleomorphic malignant cells with clear cytoplasm. A MMMT usually shows clusters of malignant glandular cells only, as malignant stromal cells seldomly exfoliate.

A

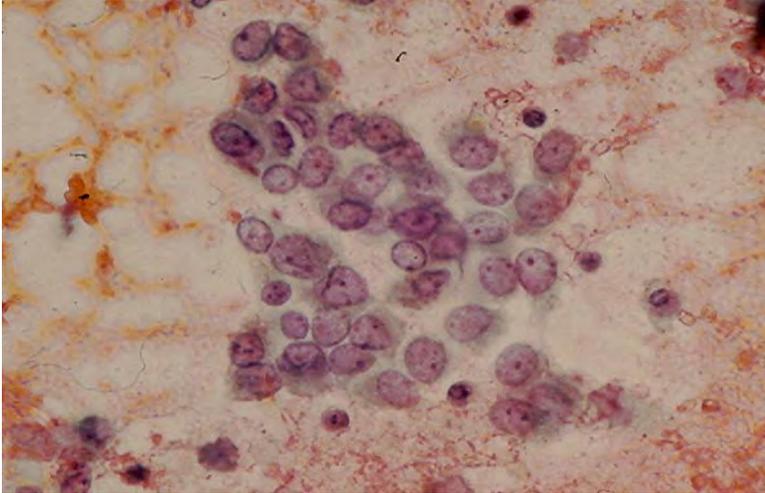

Fig. 2.5. Low-grade endometrioid adenocarcinoma of the uterus showing clustered monomorphic cells with oval nuclei and small, conspicuous nucleoli. A few tumor cells with irregular nuclear contours are also present. (Pap: A, x 200 and B, x 400).

Cervical cancer. The incidence of positive PW in cervical cancer of all stages is low, about 8%, and it is about 1% in stage IB cervical cancer. PW finding is not included in FIGO staging system for cervical cancer. Adenocarcinoma of the cervix more commonly spreads to the peritoneal cavity than its squamous cell counterpart. Adenocarcinoma cells are seen in clusters, as well as those of a non-keratinizing squamous cell carcinoma. Cells derived from a keratinizing squamous cell carcinoma are often present singly.

3. Second-look laparotomy

Patients who had chemotherapy or radiotherapy for advanced ovarian cancer and show no clinical or diagnostic imaging evidence of residual tumor may undergo a laparotomy to evaluate the response to therapy. In about 50% of cases residual tumor is identified grossly, and in 20% of patients an evidence of residual tumor is confirmed by tissue biopsy and/or PW. PW in this situation has a low sensitivity, ranging between 31 and 86%, according to several reported series.

4. Non-gynecologic malignancies

Peritoneal washing has been used to assess peritoneal spreading of gastric, pancreatic or colonic cancer at laparotomy. A positive PW, in absence of grossly visible peritoneal deposits, indicates an advanced stage disease in the above-mentioned conditions. (Fig.2.6).

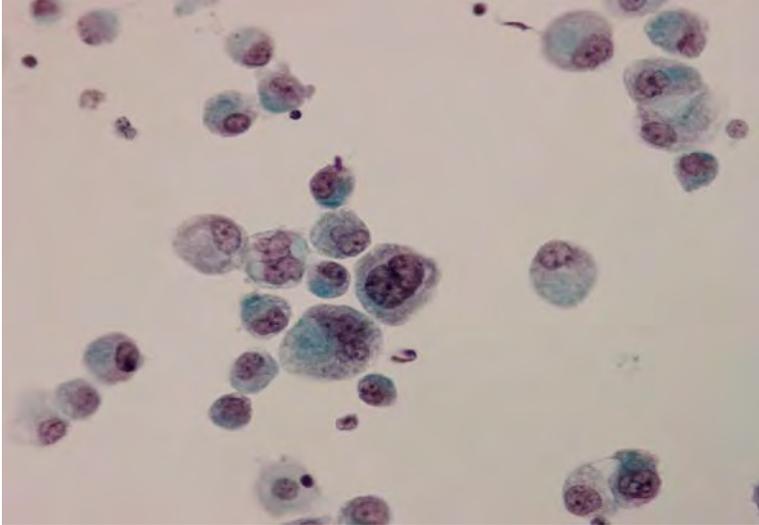

Fig.2.6. Isolated malignant cells with signet-ring cell configuration are seen in PW of a patient with an inoperable gastric linitis plastica. (Pap, x500).

DIAGNOSTIC ACCURACY AND PITFALLS

In general, PW has a low sensitivity rate, as 23 - 52% of patients with biopsy proven peritoneal metastases have a negative PW, according to the review of several reported large series by Cibas. On the other hand a positive PW in patients with a gynecologic malignant neoplasm changes the tumor surgical stage in only about 3% of cases. As a positive diagnosis may have an impact on patient management, therefore, only an unequivocally positive diagnosis is generally used for cancer staging while all other diagnostic interpretations (atypical or suspicious) are regarded as negative.

Cytologic interpretation of PW has diagnostic pitfalls. Hyperplastic mesothelium may occur in a number of benign conditions such as chronic pelvic inflammatory disease, endometriosis, endosalpingiosis, tuboovarian abscess, benign pelvic tumor, after chemotherapy and radiotherapy and it may yield cells with atypia that may mimic malignant glandular cells.

Hyperplastic mesothelial cells are usually seen in small clusters and sheets with variable degrees of nuclear atypia. In most cases the clusters and sheets of reactive mesothelial cells display enlarged, hyperchromatic nuclei with prominent nucleoli and focal nuclear crowding. (Fig. 2.7). A cluster of hyperplastic mesothelial cells may also mimic a group of nonmucus secreting malignant epithelial cells.

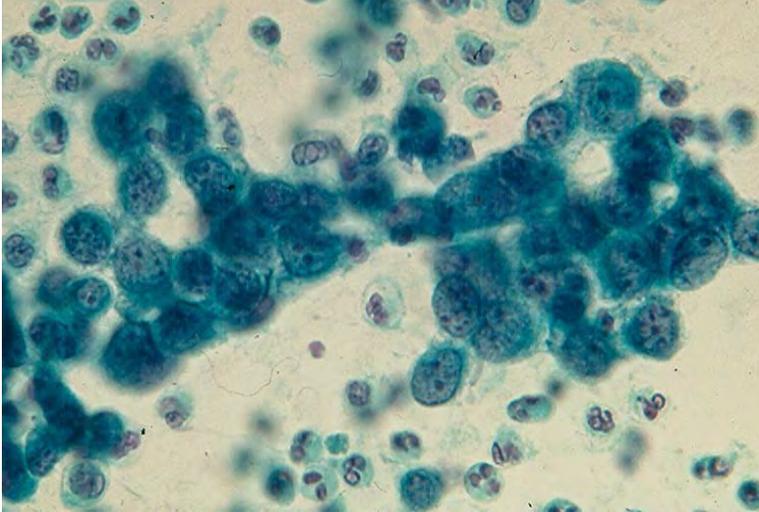

Fig.2.7. A cluster of atypically hyperplastic mesothelial cells in PW of a woman who had radical surgery for her ovarian serous carcinoma. (Pap, x 500).

The differential diagnosis between hyperplastic mesothelial cells with marked nuclear atypia and malignant glandular cells is challenging. IM studies of PW CBs are useful in this case. Reactive mesothelial cells are immunoreactive with calretinin, CK5/6, WT1 and D2-40 antibodies and negative for CEA, MOC31 and Ber-Ep4. As ovarian surface epithelium is calretinin positive, this stain should be interpreted with caution and always in conjunction with clinical and diagnostic imaging findings. Ovarian serous carcinoma cells express CK7 and p53 and negative for CK20. They can also express mesothelial markers, especially WT1. Therefore, their immunoprofile may not be useful to distinguish them from reactive mesothelial cells and cells from a diffuse malignant peritoneal mesothelioma. Mucinous tumor cells stain positively with PAS reagent with prior diastase digestion, and the common intestinal type tumor cells often show immunoreactivity with CEA, CK20 and CDX2 antibodies. Endometrial carcinoma cells are positive for estrogen receptor and vimentin and cells derived from an advanced stage endocervical adenocarcinoma are positive for CEA and p16.

In the case of *peritoneal endometriosis* a few sheets of endometrial epithelial cells and clusters of reactive mesothelial cells admixed with hemosiderin-laden macrophages may be observed. A PW CB may reveal fragments of endometrial tissue consisting of both endometrial glandular cells and stromal cells. Salpingiosis may yield atypical glandular cells in sheets or clusters with some cells displaying ciliae, and psammoma bodies may be observed.

Detection of malignant cells in PW is important. While high-grade carcinoma cells are easily identified, in difficult cases, cytohistologic correlation with the corresponding surgical specimens is necessary and strongly recommended to avoid a false-positive or false-negative cytodiagnosis.

Chapter 3

Cerebrospinal Fluid

Katherine M. Ceballos and Gia-Khanh Nguyen

Cerebrospinal fluid (CSF) cytologic evaluation was developed following the introduction of lumbar puncture in 1891 in Germany, and in the beginning, several cases of meningitis were diagnosed cytologically. Tumor cells were first reported in the CSF in 1904 and metastatic cancer cells were increasingly identified after 1908. CSF cytology is now a routine method of investigation of central nervous system (CNS) diseases, worldwide.

INDICATIONS AND GOALS

The main indications and goals of CSF cytology include:

- Investigation of patients suspected to have an infection, primary neoplasm, metastatic tumor or degenerative disorder involving the CNS.
- Assessing the treatment response of CNS tumors.

COLLECTION AND PREPARATION OF SPECIMENS

CSF is usually collected by aseptic lumbar puncture. This procedure is contraindicated in patients with increased intracranial pressure as it may cause uncal or tonsillar herniation with fatal compression of the brain stem. CSF may also be obtained from shunt drainage, from the ventricles during craniotomy, via a burr hole or by transfontanelle puncture in infants. It may be aspirated from a plastic reservoir that is connected to one of the lateral ventricles by a cannula via a burr hole. The reservoir is implanted in the subcutaneous tissue of the scalp and it is used for injection of chemotherapeutic agents to treat brain cancers. As cells in the CSF tend to degenerate quickly, the fluid samples must be processed within 30 min of procurement. Usually, a 3-tube technique is used. Tube # 1 is frequently contaminated with blood and is therefore used for serology and biochemical tests, tube # 2 is used for microbiological cultures, if an infection of the central nervous system is suspected, and tube # 3 is used for cytologic evaluation. Refrigeration at 4^o C may preserve cell details up to 48 hr. If a delay in processing CSF is anticipated, the addition of an equal amount of 50% ethanol is recommended. Fresh and unfixed specimens are usually prepared by the usual cytopspin technique using a relatively slow speed: 500 rpm for 5 min. The smears obtained are air-dried or fixed in 95% ethanol for staining with the Wright method or the Papanicolaou technique, respectively. Usually, 3- 4 mL of CSF is required for a confident diagnosis. A repeat lumbar puncture should be made if the first CSF sample is negative and there is strong

clinical suspicion of disease. According to some studies, the false-negative rate of CSF cytology decreases with an increased amount of CSF obtained and a decrease in time from specimen procurement to specimen processing.

NORMAL CSF CYTOLOGY AND CONTAMINANTS

Normal CSF is scanty in cellularity. In a routinely prepared specimen, rare benign lymphocytes and macrophages are noted. Choroid plexus and ependymal cells are rarely seen in specimens obtained by lumbar puncture. They are present in large numbers in cell samples aspirated directly from the cerebral ventricles. Normal ependymal cells are round or oval in shape with a moderate amount of granular cytoplasm and round or oval, centrally located nuclei with inconspicuous nucleoli. These cells are either seen singly or in small sheets or clusters. Minute normal brain tissue fragments may be present in specimens aspirated from cerebral ventricles. Specimens obtained by lumbar puncture may be contaminated with bone marrow cells aspirated from a vertebral body or cartilaginous tissue fragments and chondrocytes from an intervertebral disc.

INFLAMMATORY DISEASES

1. Bacterial meningitis is an acute infection commonly caused by *Neisseria meningitides* (meningococcus), *Hemophilus influenza*, *Streptococcus pneumoniae* (pneumococcus) and *Listeria monocytogenes*. CSF samples show numerous polymorphonuclear leukocytes and necrotic debris. A Gram stain may reveal the causative organisms, but culture of the fluid is required for proper bacterial identification.

2. Aseptic meningitis is a misnomer but the term has been used extensively in medical practice. Most cases are caused by an infectious microorganism, most commonly a virus. The CSF findings are non-specific and consist of increased numbers of lymphocytes and macrophages with occasional atypical lymphoid cells showing larger nuclei with irregular nuclear contours, dispersed chromatin and conspicuous nucleoli. Cells with viral morphologic changes, as seen in herpetic and cytomegalovirus infections of the lung or female genital tract, are not usually observed. This form of meningitis may also be caused by some bacteria (*Borrelia burgdorferi*, *Treponema pallidum*, *Mycobacterium tuberculosis*, *Mycoplasma pneumoniae*), some fungi (*Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*), a variety of drugs, systemic inflammatory diseases (Behcet disease, sarcoidosis), and degenerative CNS diseases. Similar nonspecific cytologic changes may be seen in patients with headaches, seizures, multiple sclerosis or Guillain-Barre' syndrome.

3. Cryptococcal meningitis is caused by *Cryptococcus neoformans*. This infection can occur in both healthy and immunocompromised hosts. The CSF shows an increased number of lymphoid cells and *Cryptococcus neoformans* may be seen in routinely stained CSF preparations. This microorganism has a round yeast form, 5-15 microns in

greatest dimension and may show asymmetric, narrow-based budding. (Fig.3.1). It can be better visualized in CSF stained with Gomori methenamin-silver or PAS reagent.

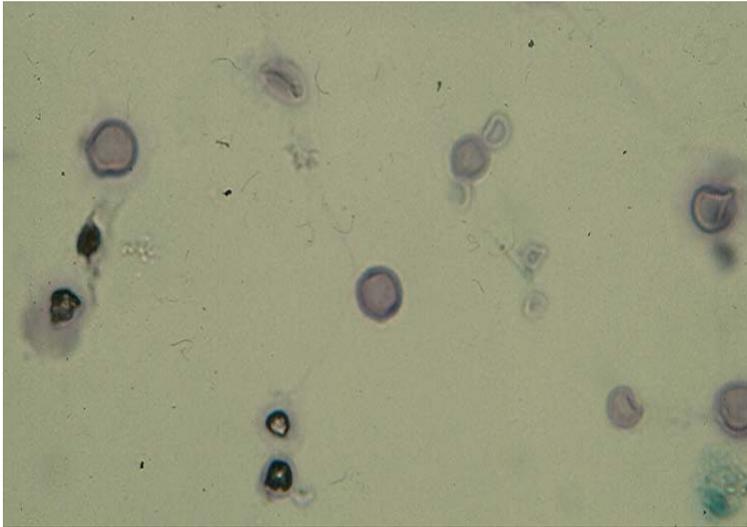

Fig.3.1. Cryptococcal meningitis showing in CSF thick-walled yeasts with budding. (Pap, x 800).

NEOPLASMS

Of the tumors involving the CSF, metastatic cancers are more common than primary tumors. Malignant neoplasms arising from virtually any anatomic site in the body may metastasize to the brain, spinal cord and leptomeninges. Cancers of the lung, breast, stomach, as well as cutaneous melanoma, lymphoma and leukemia are the tumors that most frequently spread to the CNS. Tumor cells will not be present in the CSF unless the leptomeninges or ventricular system is invaded. In clinical practice, the primary cancer is known in over 90% of patients with malignant cells in the CSF. However, in the remaining cases, positive CSF is the presenting feature of a clinically occult cancer.

Primary CNS Tumors

Primary CNS tumors are much less common than metastatic tumors. Cells from an intracerebral tumor are only present in the CSF if the ventricular system or the arachnoid space is invaded. In adults, cells from a high-grade astrocytoma such as anaplastic astrocytoma or glioblastoma multiforme and cells from primary lymphoma are commonly seen in the CSF. In children, medulloblastoma is the most common tumor associated with a positive CSF.

1. Astrocytoma is the most common intracerebral glial tumor. The tumor is histologically classified into 3 histologic types/grades: well-differentiated astrocytoma, anaplastic astrocytoma and glioblastoma multiforme, depending on the presence of cellular pleomorphism, necrosis and vascular proliferation.

Well-differentiated astrocytoma is a slow-growing tumor and rarely exfoliates its cells in the CSF. In cases with positive CSF a small number of single large tumor cells with enlarged nuclei and small nucleoli may be observed.

Anaplastic astrocytoma may shed pleomorphic malignant cells into the CSF, either singly or in loose aggregates. (Fig.3.2). The tumor cell cytoplasm is positive for Glial fibrillary acidic protein and negative for epithelial markers such as cytokeratin.

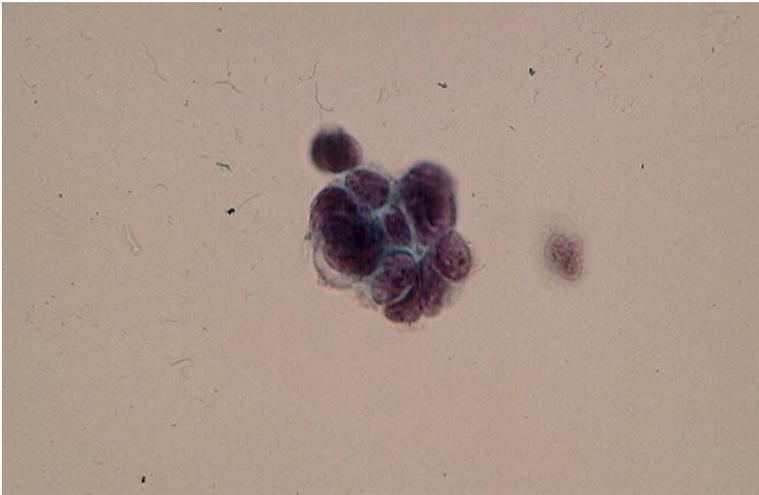

Fig.3.2. Anaplastic astrocytoma showing in CSF a tight cluster of malignant cells with scant cytoplasm and pleomorphic nuclei. (Pap, x 500).

Glioblastoma multiforme involving CSF shows pleomorphic malignant cells with bizarre single or multiple nuclei and macronucleoli. These cells may express Glial fibrillary acidic protein.

2. Medulloblastoma is a small blue cell tumor and is the most common intracranial tumor in children. Cytologically, involved CSF contains single and clustered small tumor cells with nuclear molding. (Fig.3.3).

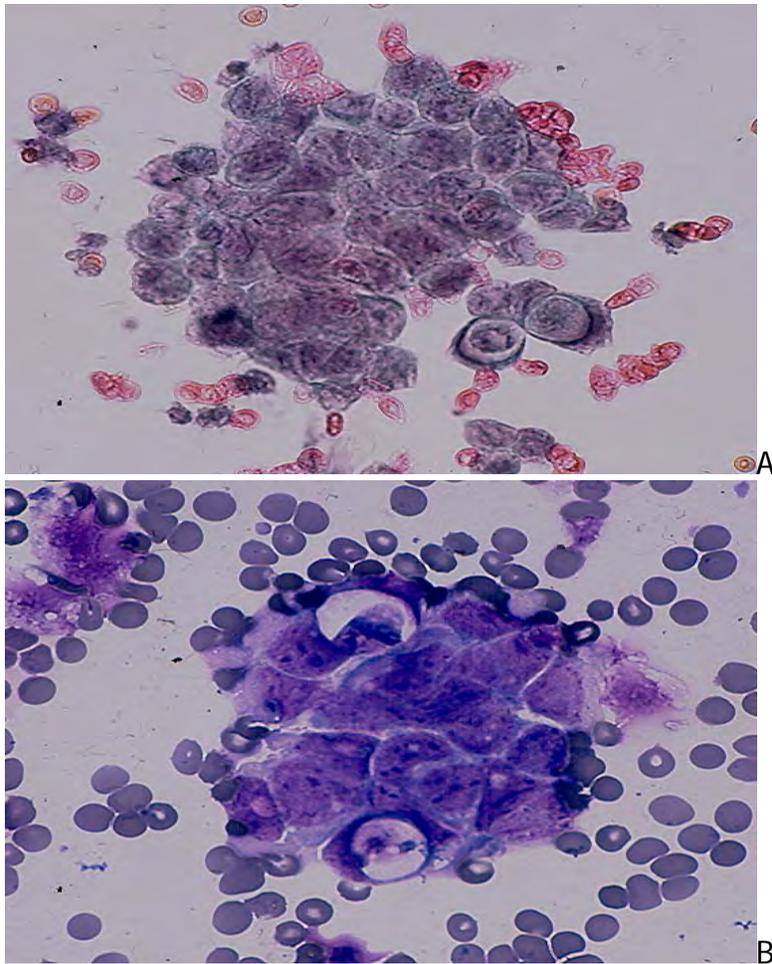

Fig.3.3. Medulloblastoma showing in CSF small cancer cells with scant cytoplasm, round or irregular nuclei in a tight cluster with nuclear molding. (A: Pap, x 800; B: MGG, x 800).

3. Ependymoma and Choroid plexus tumors occur in the ventricular system with the 4th ventricle being the most common location. These neoplasms are more common in children and adolescents than in adults. Ependymoma and choroid plexus papilloma are cytologically similar and exfoliate single and clustered cells into the CSF. They are cuboidal cells with round nuclei and scant cytoplasm. Choroid plexus carcinomas exfoliate cells indistinguishable from those of a metastatic adenocarcinoma. (Fig.3.4).

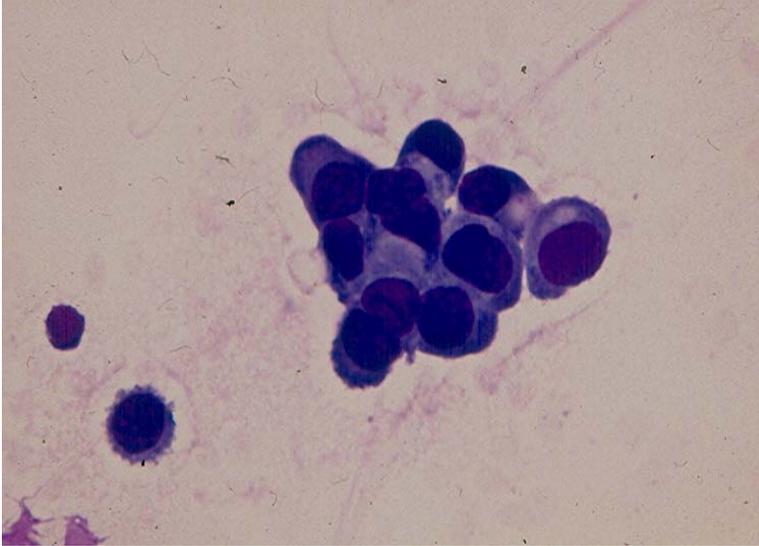

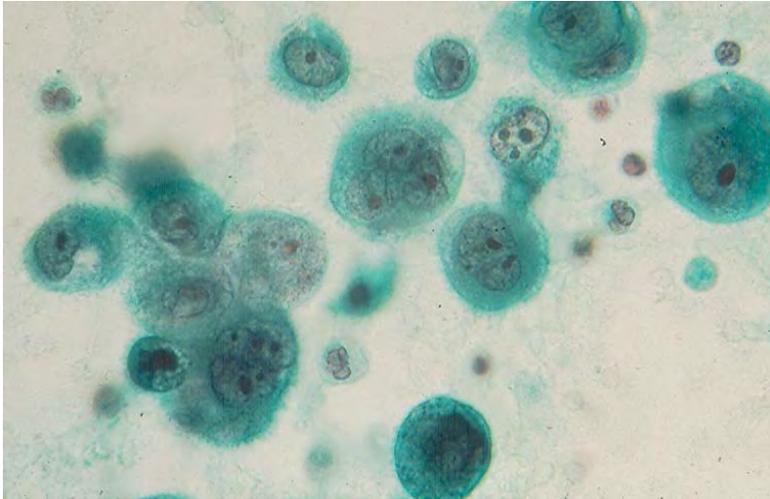

Fig.3.4. Choroid plexus carcinoma showing in CSF single and clustered malignant epithelial cells. (MGG, x 600).

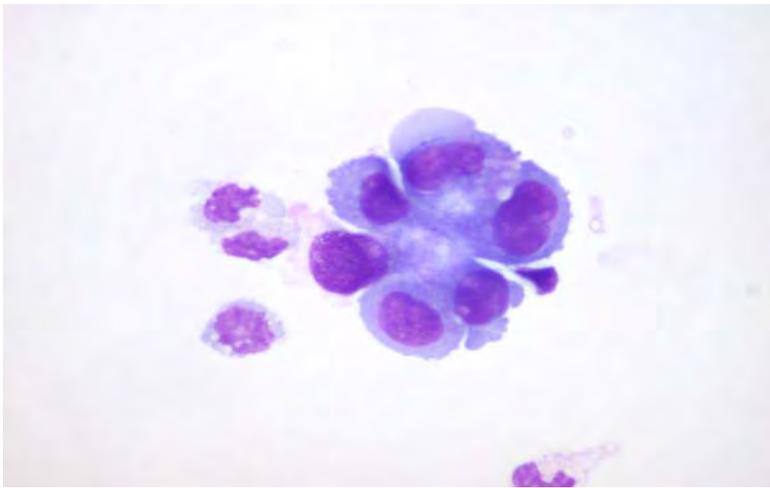

4. Other Tumors. *Germ cell tumors* can rarely arise intracranially and when they do are usually located in the pineal region. Histologic types include embryonal carcinoma, seminoma/dysgerminoma, yolk sac tumor, teratoma and choriocarcinoma. The tumors may be of pure or mixed histologic type. *Primary non-Hodgkin lymphoma*, an uncommon CNS tumor that usually arises in an immunocompromised patient. The above-mentioned neoplasms may invade the ventricular system and exfoliate its cells in the CSF. *Meningioma, pituitary adenoma and sarcomas* rarely shed their cells into the CSF.

Metastatic Tumors

1. Bronchogenic carcinoma of all types can metastasize to the CNS and exfoliate their cells in CSF. Adenocarcinoma and small cell carcinoma are the most common tumors associated with a positive CSF. Malignant glandular cells are usually seen singly and have well-defined cytoplasm and prominent nucleoli. (Fig.3.5). Cells derived from a small cell carcinoma may be single or in small cohesive clusters with nuclear molding. (Fig. 3.6).

A

B

Fig.3.5. Metastatic bronchogenic adenocarcinoma showing in CSF malignant, pleomorphic epithelial cells with prominent nucleoli singly and in cluster. (A: Pap, x 500 and B: MGG, x400)

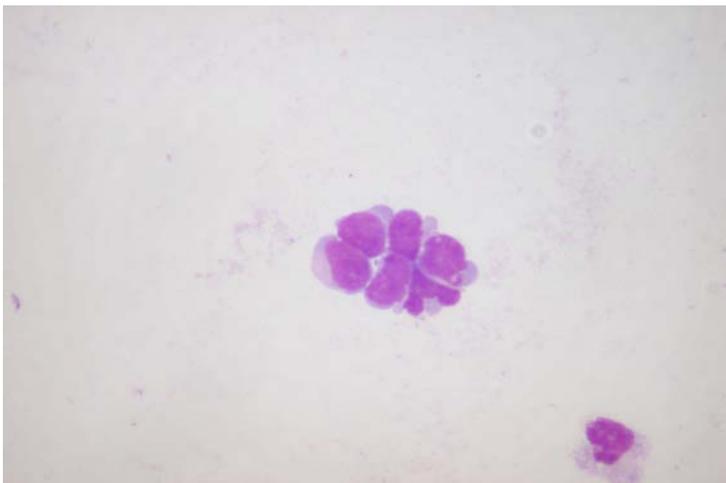

Fig.3.6. A cluster of metastatic small cell carcinoma cells in CSF showing nuclear molding. (MGG, x 400)

2. Mammary carcinoma of ductal or lobular origin may metastasize to the CNS. It exfoliates in CSF predominantly single, monomorphic malignant glandular cells with conspicuous nucleoli. Tumor cells in cohesive clusters and in linear rows are rarely observed. Cells derived from a lobular carcinoma are smaller than those of a ductal carcinoma. (Fig.3.7 and Fig.3.8).

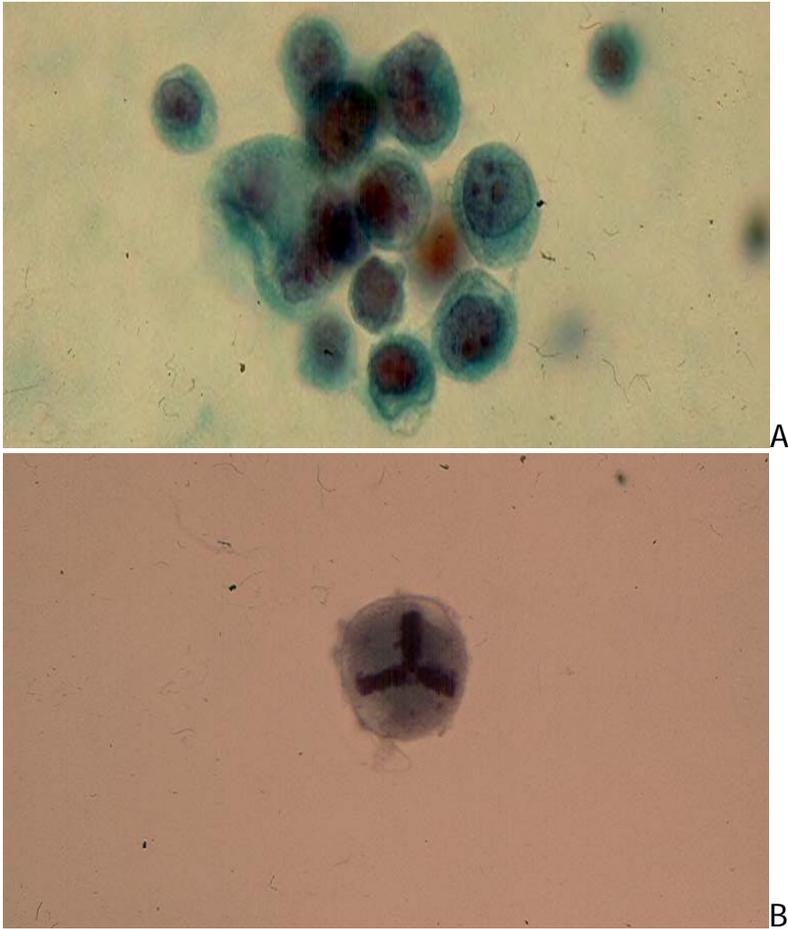

Fig.3.7. Single and loosely clustered monomorphic malignant glandular cells with conspicuous nucleoli (A) and a tumor cell with a tripolar mitotic figure (B) from a metastatic mammary duct carcinoma. (Pap, x 500).

Fig.3. 8. Metastatic mammary lobular carcinoma showing in CSF small tumor cells present singly and in a linear arrangement. A conspicuous nucleolus is noted in one cell. (Pap, x 400).

3. Gastrointestinal carcinomas rarely metastasize to the CNS. An example of a metastatic signet-ring cell carcinoma of the stomach involving the CSF is pictured below. (Fig.3.9).

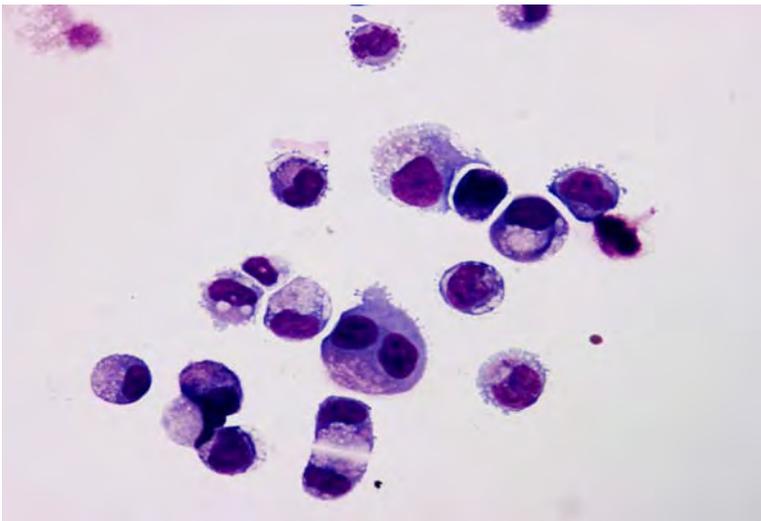

Fig.3.9. Metastatic gastric carcinoma showing in CSF isolated cancer cells with signet-ring cell morphology. (MGG, x 400).

4. Melanoma. Metastatic melanoma to the CNS, regardless of its primary site, typically shows in CSF single, large malignant cells with defined cytoplasm and enlarged, oval nuclei with macronucleoli. Intracytoplasmic melanin pigment granules and intranuclear cytoplasmic inclusions may be observed. Melanoma is a great mimic of other tumors and can have various cytologic appearances, including a spindle-cell morphology. A positive cytoplasmic reaction with HMB-45 or Melan A antibodies will practically support a melanocytic differentiation.

5. Non-Hodgkin Lymphoma may involve the CNS. The cytologic appearance of the tumor cells in CSF varies with the type of lymphoma but the cells are usually present singly and show monomorphic nuclei with nuclear indentation and protrusion. Hodgkin disease rarely involves the CNS. (Fig.3.10)

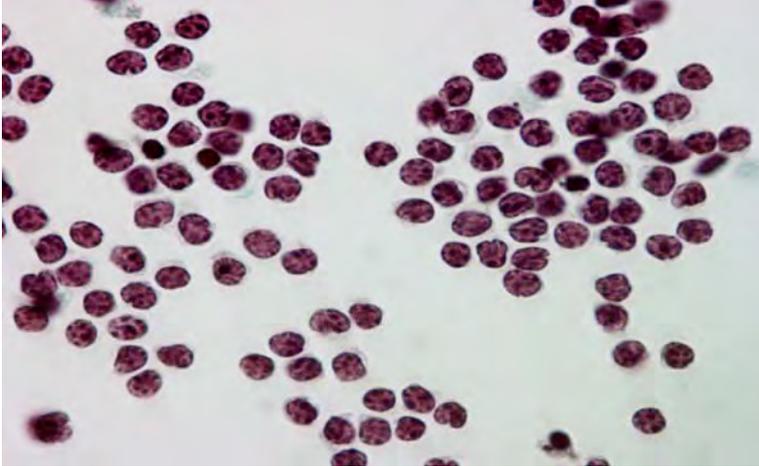

Fig.3.10. Metastatic non-Hodgkin lymphoma to the brain showing in CSF isolated, monomorphic lymphoid cells with nuclear indentation. (Pap, x 400).

5. Leukemia of all types may spread to the leptomeninges. As in non-Hodgkin lymphoma, leukemic cells are more easily identified and classified in Wright-stained preparations.

Acute lymphoblastic leukemia is the most common malignancy in children but it may affect adult patients. CNS involvement is common and often clinically silent. It is present at initial leukemic diagnosis in about 5% of cases. The disease responds well to chemotherapy and has a favorable prognosis. Numerous single monomorphic lymphoblasts with prominent nucleoli are present in the CSF. (Fig.3.11).

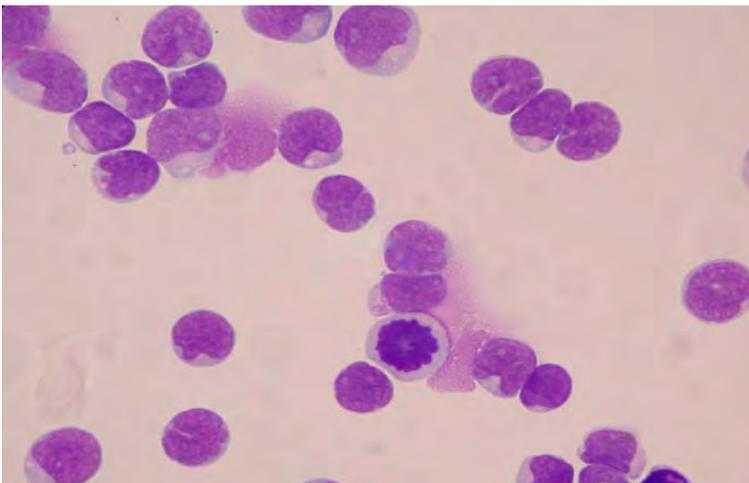

Fig.3.11. Numerous monomorphic lymphoblasts with nuclear clefts and prominent nucleoli are present in CSF of a patient with acute lymphoblastic leukemia.

(Wright, x 1000). Courtesy of Dr. J. Ford, Vancouver, BC, Canada.

Acute myeloid leukemia is more common in adults than in children. Its leptomeningeal involvement is less common than in acute lymphoblastic leukemia. Cells derived from an acute myeloid leukemia cells are, in general, large and show round or highly irregular nuclei, fine chromatin and prominent nucleoli. Intracytoplasmic azurophilic granules may be observed in MGG-stained cells. (Fig.3.12).

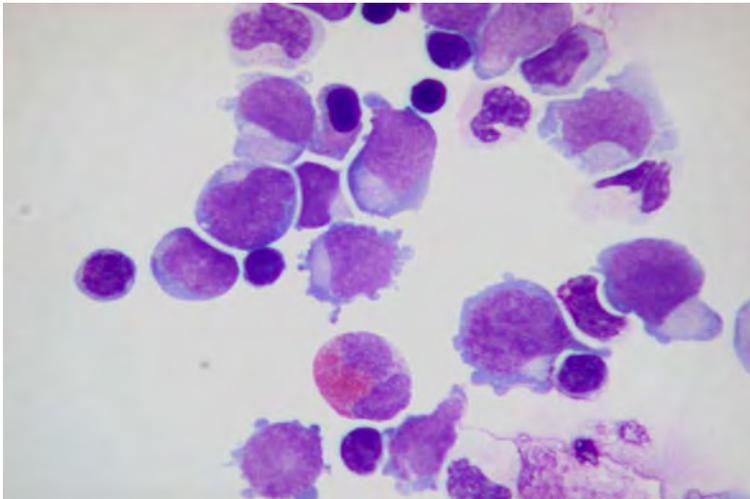

Fig.3.12. Acute myelogenous leukemia showing in CSF numerous myeloblasts present singly and in aggregates. Intracytoplasmic azurophil granules are seen in one of the myeloblast. (Wright stain, x 1000).

Chronic lymphocytic leukemia is predominantly an adult disease. It has a protracted clinical course and it rarely involves the CNS. The tumor cells are B-cells and morphologically similar to small lymphocytes. They should be distinguished from reactive lymphoid cells (T-cells) by cell marker studies.

Chronic myelogenous leukemia apparently does not involve the CNS. However, some patients develop a transformation to acute myelogenous leukemia with leptomeningeal spread.

DIAGNOSTIC SENSITIVITY AND ACCURACY

1. CSF cytology is regarded as a test with moderate sensitivity and high specificity. The sensitivity of CSF cytology in detecting cancer cells is substantially higher when two samples are evaluated. The sensitivity of one sample is 54% while the combined sensitivity of two samples is 84%. Additional samples do not significantly increase the diagnostic sensitivity.

2. For *primary brain tumors* CSF cytology has a sensitivity of about 32%. The diagnostic accuracy rate varies widely, with medulloblastoma being the most common tumor that is correctly diagnosed (80% accuracy rate).

3. For *metastatic cancers* the diagnostic sensitivity of CSF cytology is about 53.3%, with lung and breast carcinomas being the most commonly diagnosed malignancies.

4. For *lymphoma and leukemia* the diagnostic accuracy rate of CSF cytology is about 65%.

5. *False-positive diagnosis* is about 2-3%, and the most common cause of a false-positive diagnosis is the overdiagnosis of lymphoma in cases of aseptic meningitis.

DIAGNOSTIC PITFALLS

CSF cytology has several diagnostic pitfalls:

Benign cells of choroid plexus may be mistaken for those of a metastatic adenocarcinoma or choroid plexus carcinoma. This occurs mainly in cell samples aspirated from the cerebral ventricular system and rarely in samples taken by lumbar puncture.

Bone marrow cells may incidentally be sampled by needling the body of a lumbar vertebra. These cells may be misinterpreted as those of a chronic myelogenous leukemia by a novice. However, the presence of immature red blood cells and megakaryocytes is a strong evidence in favor of normal bone marrow cells.

Chondrocytes from an intervertebral disk may be sampled by lumbar puncture. They may be mistaken for metastatic glandular cells by an inexperienced observer. The bland nuclei and absence of macronucleoli of chondrocytes are helpful features to rule out a metastatic adenocarcinoma.

Urine in Urinary Tract Lesions

Gia-Khanh Nguyen

Urine cytology has a long history of development that can be traced back to the 19th century. In 1856, Lamb of Prague reported on the microscopic findings in urine sediments of a few cases of bladder and urethral tumors. Subsequently, Beale of England published in 1864 a book on urine cytology in which cancer cells were described in detail. Since that time reports on cytology of urinary tract cancers were sporadically encountered in the medical literature. In 1945 Papanicolaou and Marshall published in Science a paper reporting on cytologic examination of urine sediments in 83 patients and in the 1950s Crabbe published extensively on the application of voided urine cytology to the surveillance of workers in dyestuff industries in England. In the 1960s, Koss and his coworkers had several publications on the diagnostic value and limitations of voided urine and also introduced the concept of nonpapillary carcinoma in situ as the principal precursor lesion of invasive carcinoma of the bladder. Currently, several hundreds papers on urine cytology of have appeared in the medical literature each year.

INDICATIONS AND GOALS

1. Investigation of hematuria
2. Follow-up of patients treated for urothelial cancer
3. Screening for bladder cancer in high-risk workers

COLLECTIONS OF CELL SAMPLES

Five types of fluid cell sample are currently used for investigation of urinary tract lesions.

1. Voided urine samples cells from the whole urinary tract. Early morning voided urine specimens are not optimal for cytologic evaluation as exfoliated urothelial cells tend to undergo degenerative changes in a low pH and hypertonic environment. A mid-stream and freshly voided urine sample should be collected in a clean container 3 to 4 hr after the patient has last urinated. In women, to minimize the contamination with vaginal secretions a voided mid-stream, "clean-catch" urine sample should be collected after washing the perineum. Usually, 50 -100 mL of urine is required for a proper cytologic study. The most useful urine specimen for detection of cancer cells is a random voided urine, with at least 3 samples collected over a 2 week- period.

2. Catheterized urine. This type of cell sample has no better diagnostic value than a voided urine. Catheterized urine sample is usually collected from an indwelling bladder catheter and is often pooled at room temperature for several hours. Therefore, cell degeneration may be marked. Catheterized urine usually contains large fragments of urothelium that are mechanically exfoliated by the catheter tip.

3. Bladder washing. The specimen is obtained by irrigating the urinary bladder with 5 to 10 pulses of 50 mL of sterile normal saline via a catheter. It is collected before cystoscopy and biopsy of any suspicious bladder lesions. This type of specimen is highly cellular with well-preserved cells.

4. Renal pelvis and ureter washings. Washing renal pelvis or ureter is performed if a tumor is suspected in these locations. This procedure is done during cystoscopy. Usually cell samples are taken from both right and left ureters and renal pelvises. The specimens are usually cellular and contain large fragments of urothelium.

5. Intestinal conduit. Small intestinal conduits are created in patients who undergo a radical cystectomy for bladder cancer. Urine samples from intestinal conduits are cellular and full of degenerated intestinal epithelial cells. Screening these cell samples is important because patients with bladder cancer have an increased risk for developing new cancers in their ureters and renal pelvises.

SPECIMEN PROCESSING

Epithelial cell morphology is well preserved in unfixed urine kept at room temperature for a long period of time. If the urine specimen is processed within 12 hr no preservative is needed. Refrigeration of urine samples is required if the specimens are processed between 12 and 24 hr. If a longer delay in specimen processing is anticipated urine samples should be mixed with an equal volume of 50% ethanol or Saccomanno fixative (50% ethanol and 2% carbowax).

Usually, a vial of 10 mL is centrifuged at 1800 rpm for 10 min. The supernatant is discarded and the remaining 1 mL sediment is used for the preparation of 2 - 4 cell films/smears by the routine cytopsin technique. If the cell button is judged to be too thick, it can be gently smeared using a thin coverslip. Washing the sediment with normal saline may be necessary to remove necrotic debris before smear preparation. Bloody smears may be fixed in Carnoy solution for 3 to 5 min to lyse red blood cells. In addition to the widely available cytopsin technique, direct smears prepared from the urine/fluid sample sediment, membrane filtration technique or thin layer method may also be used for cytologic evaluation. The prepared smears obtained are fixed in 95% ethanol and stained by the Papanicolaou method.

NORMAL URINARY TRACT

Renal pelves, ureters, urinary bladder and urethra are lined by a single layer of urothelium consisting of 5 to 7 layers of urothelial or transitional cells: basal, intermediate and superficial or umbrella cells. The bladder trigone is covered by a nonkeratinizing squamous epithelium in 50% of women and in a smaller percentage in men. In premenopausal women the trigone squamous epithelium may show cyclic changes. (Fig. 4.1).

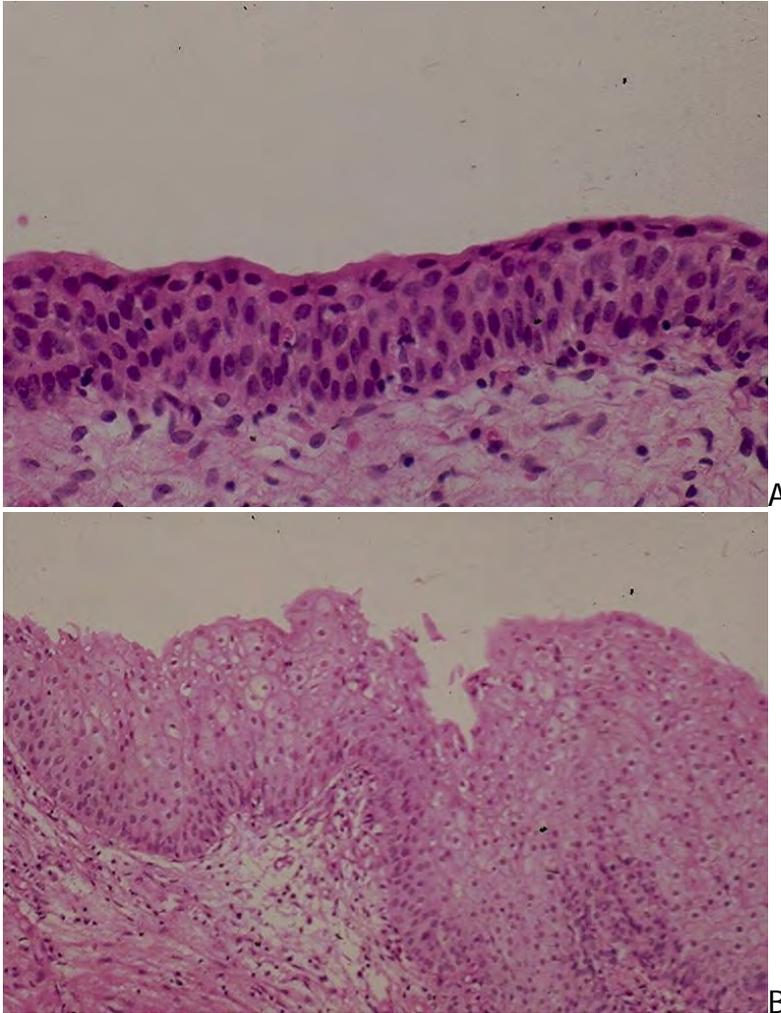

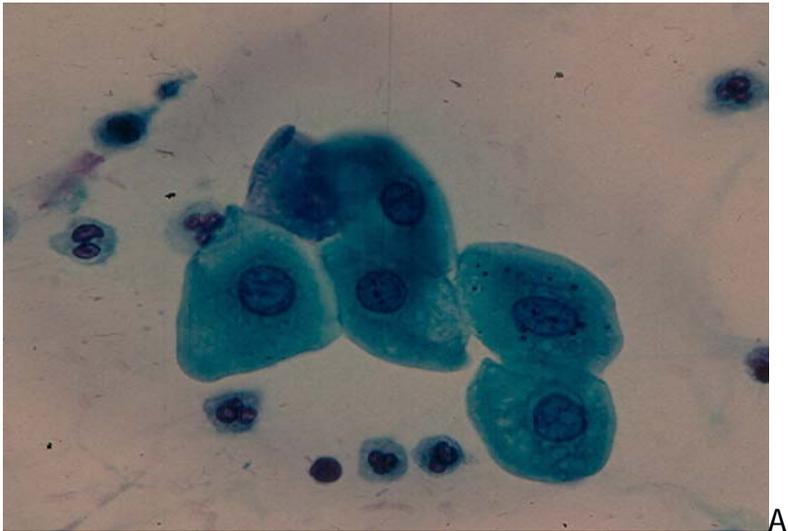

Fig. 4. 1. A. Histology of normal urothelium. (HE, x 200)

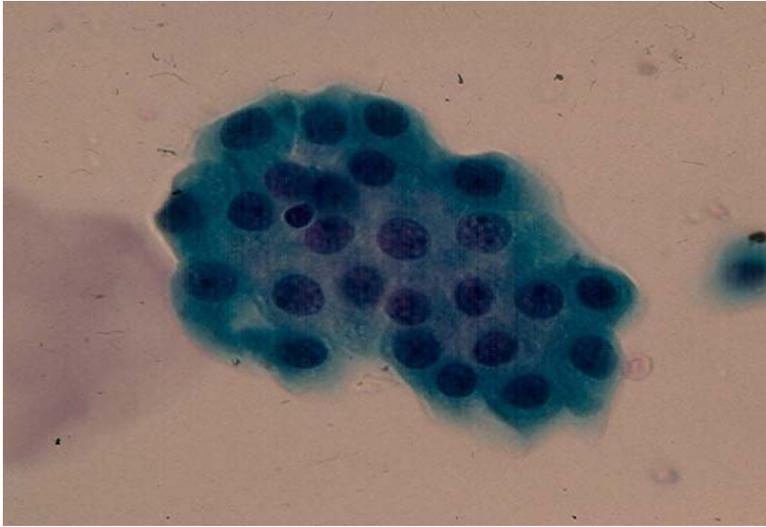

B. Histology of normal squamous epithelium in bladder trigone. (HE, x 100).

In urinary tract fluid samples both urothelial and squamous cells are seen. The *intermediate urothelial cells* are commonly present singly. They are polygonal in shape with abundant, dense, homogenous, basophilic, well-defined and slightly condensed at periphery and measure about 229 sq. microns on average, and their nuclei have a mean area of about 40 sq. microns. The *basal cells* are small and cuboidal in shape with a dense cytoplasm and monomorphic and slightly hyperchromatic nuclei. The cells measure

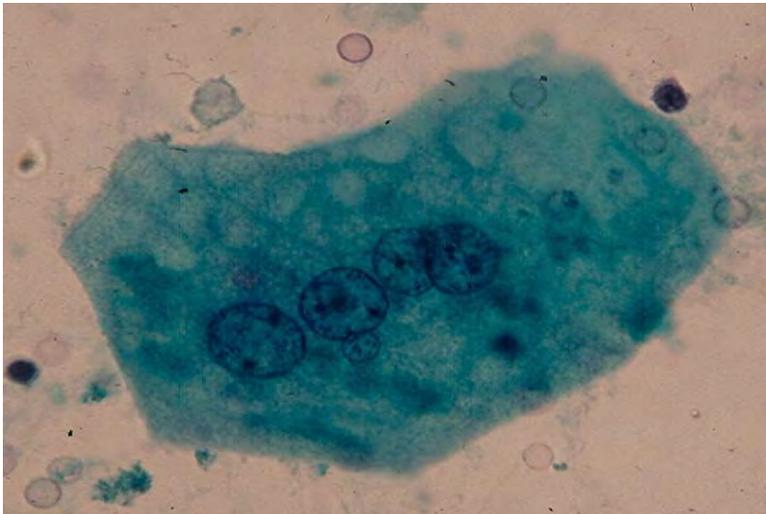

82 sq. microns on average and their nuclei have a mean surface area of 24 sq. microns. Umbrella cells (superficial cells) are large, multinucleated and show abundant cytoplasm that is commonly vacuolated. They may show one flat or concave surface, corresponding to the bladder lumen. Squamous cells are large polygonal cells with well-defined and thin cytoplasm without evidence of keratinization. They derive from the bladder trigone or distal part of the urethra. (Fig. 4.2). Urothelial cells with columnar configuration may be observed and these cells are seen singly, in small clusters or rows. (Fig. 4.3).

Voided urine is usually less cellular than specimens obtained by bladder catheterization and washing. In about 20% of normal voided urine samples urothelial cell clusters are present. Rarely prostatic cells, seminal vesicle cells, spermatozoas and corpora amylacea are seen in male urine. Prostatic cells are cuboidal in shape with round nuclei and occasional small nucleoli. They usually occur in small sheets or clusters. Seminal vesicle cells may rarely be seen and they display atypical nuclei. They usually show intracytoplasmic brown pigment granules. As no criteria for adequacy or satisfactory urine cell samples have been defined for cytologic evaluation, a specimen is regarded as unsatisfactory or nondiagnostic if urothelial cells show marked degenerative change or are largely obscured by blood, inflammatory exudate and abundant squamous cells from vaginal secretion.

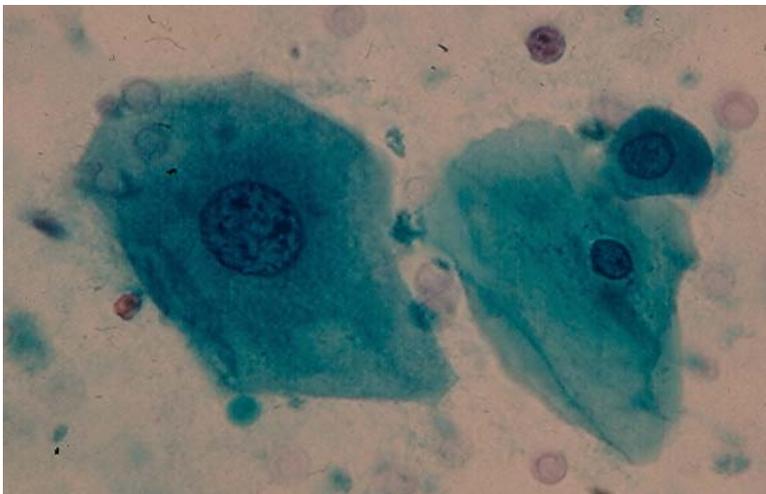

B

C

D

Fig. 4.2. Normal urine cells. (Pap: A to D, x 500).

A. Intermediate urothelial cells showing thick, well-defined cytoplasm and oval nuclei.

B. A small monolayered sheet of polygonal basal urothelial cells.

C. A large multinucleated umbrella cell with a concave cytoplasmic border.

D. An intermediate squamous cell with oval nucleus and chromatin clumping, a superficial squamous cell with a small pyknotic nucleus and a small parabasal cell.

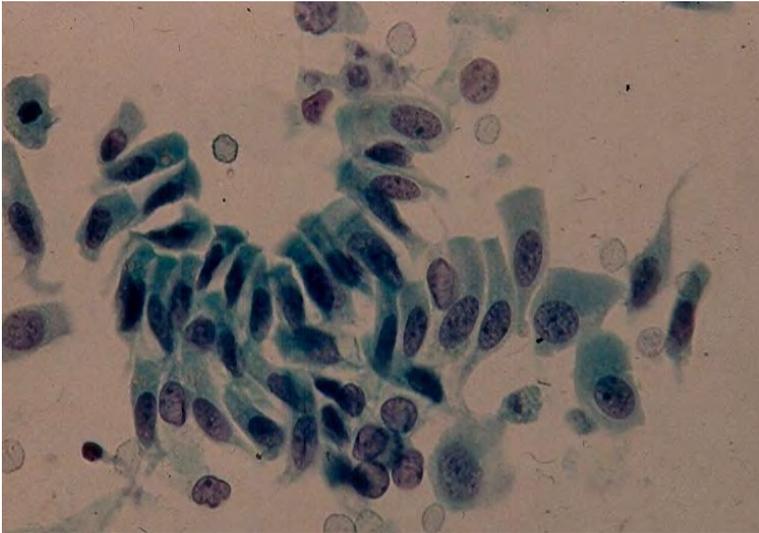

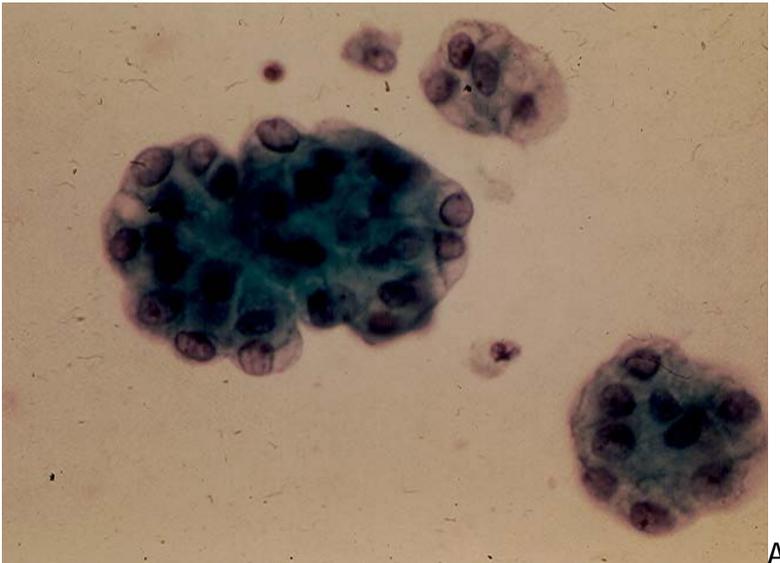

Fig. 4.3. Benign columnar urothelial cells present singly, in row or loose cluster. (Pap, x 500).

In specimens collected by *bladder catheterization or washing* several large tridimensional clusters and sheets of urothelial cells are present. (Fig. 4.4). These cell clusters and sheets are large urothelial fragments that are mechanically exfoliated by the catheter tip.

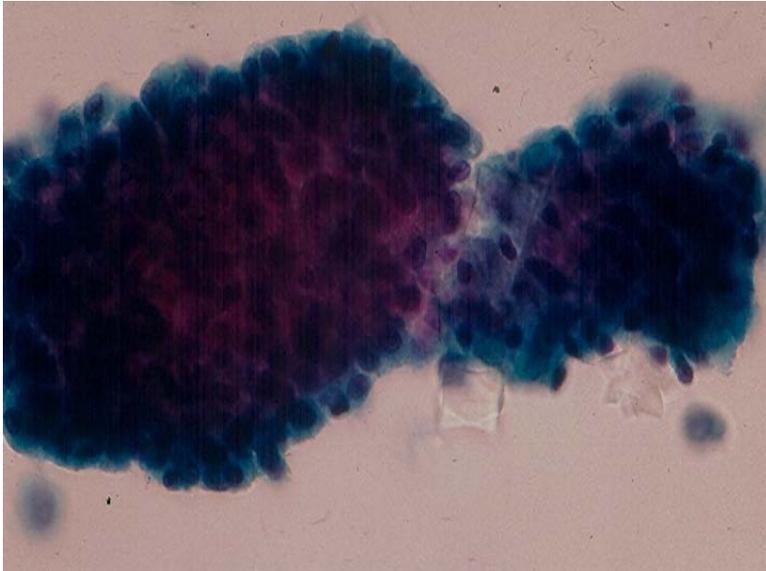

Fig. 4.4. Urothelial cells in small and large tridimensional clusters with smooth lobulated contours. (Pap: A, x 400; B, x 200).

Degenerating urothelial cells with round, eosinophilic cytoplasmic inclusions of varying sizes (Melamed-Wolinska bodies) have no diagnostic value in urine cytology. Renal tubular cells exfoliate regularly in small number and they appear as small cuboidal cells with small, oval and bland nuclei. These cells are usually seen singly or in small groups consisting of 3 to 5 cells. They are usually ignored by the observer and they may be mistaken for basal urothelial cells. Cells from renal proximal convoluted tubules are larger than those of from distal convoluted or collecting tubules and have a granular cytoplasm. The reader is referred to Chapter 5 for illustrations of renal tubular cells.

BENIGN CONDITIONS

1. Casts are formed by precipitation of protein in renal tubular lumens. Casts without entrapped cells are called hyaline casts. When leukocytes, erythrocytes or epithelial cells are present, the cast will be named as leukocytic, erythrocytic or epithelial cast, respectively. The reader is referred to Chapter 5 for illustrations of urinary casts.

2. Crystals are also formed by precipitation of some chemical materials in urine. Crystals are generally identified on morphologic basis, and they are more easily seen in unstained urine sediments under bright-field microscope and are classified as nonpathologic and pathologic. Specific identification of urine crystals is not required in diagnostic cytology and it is generally done by the Routine Urinalysis Service. The most commonly encountered crystals are uric acid crystals which are pleomorphic. Other crystals may retain their characteristic features in fixed urine, such as triple phosphate crystals with coffin lid configurations. (Fig.4.5).

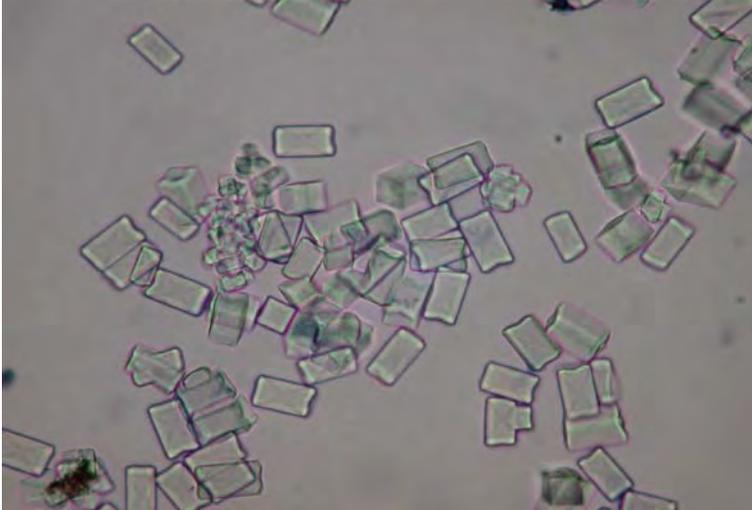

Fig.4.5. Triple phosphate crystals with coffin lid configuration. (Pap, x 200).

3. Infections of the urinary tract can be caused by bacteria, viruses and fungi.

Acute bacterial infection is characterized by the presence of numerous polymorphonuclear leukocytes in urine sediments. Atypical urothelial may display cellular atypia with slight nuclear enlargement but the nuclei remain oval in shape with bland chromatin and preserved N/C ratio. Nuclear membrane may become prominent, and single or multiple conspicuous nucleoli may be observed. Repair urothelial cells may be seen in sheets or singly. They show enlarged and prominent nucleoli, but their N/C ratio is preserved.

Fungal infection of the urinary tract is most commonly caused by monilia. The urine sediment in this case shows easily identifiable pseudohyphae and yeasts. Fungal casts may be observed in patients with renal fungal infection.

Viral infection of the urinary tract are rare and may be caused by cytomegalovirus, human polyomavirus and herpes simplex virus, and cells with characteristic cellular changes may be observed in urine sediments:

- Cytomegalovirus infection is characterized by cells with large intranuclear basophilic inclusions with halos.
- Human polyomavirus infection is characterized by cells with large homogenous, dark nuclear inclusions with or without halos. (Fig. 4.6).
- Herpes simplex virus infection shows giant multinucleate cells with molded, homogenous, ground-glass nuclei. In doubtful cases immunostaining with commercial Herpes antibody will be helpful to confirm or rule out a herpetic infection.

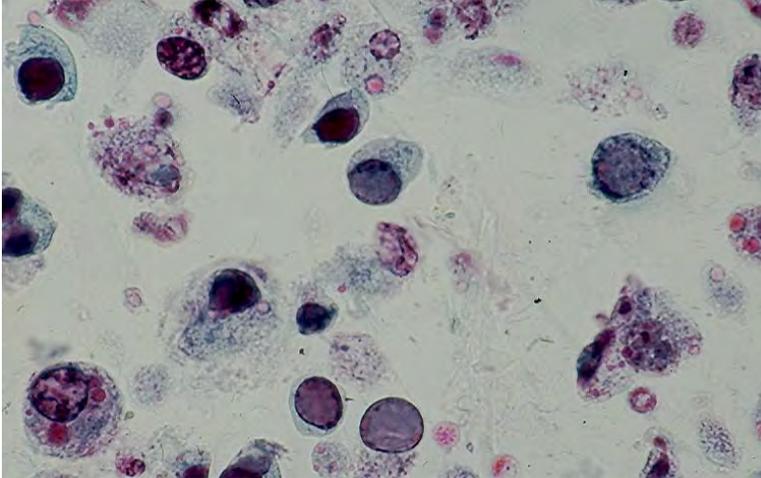

Fig. 4.6. Human polyomavirus infection showing cells with dark, homogenous structureless nuclei without nucleoli. (Pap, x 500).

Parasitic infection of the lower urinary tract caused by *Schistosoma hematobium* is endemic in Egypt, but it may be seen in South East Asian countries. The disease is not encountered in North America, but it may be encountered in immigrants from the aboved-mentioned regions. Ovum of *Schistosoma hematobium* has a terminal spine and can be easily identified in a Papanicolaou-stained urine sediment. Infection caused by *Schistosoma mansoni* is uncommon and it may occur in conjunction with *Schistosoma hematobium* infection. Ovum of *Schistosoma mansoni* shows a lateral spine. Cystitis caused by *Trichomonas vaginalis* is usually secondary to urethral infection. Pear-shaped or ovoid parasites with or without flagellae and intracytoplasmic minute eosinophilic granules may be observed. *Trichomonas* organisms seen in voided urine samples in women most commonly represent a contamination from the genital tract infection. (Fig. 4.7).

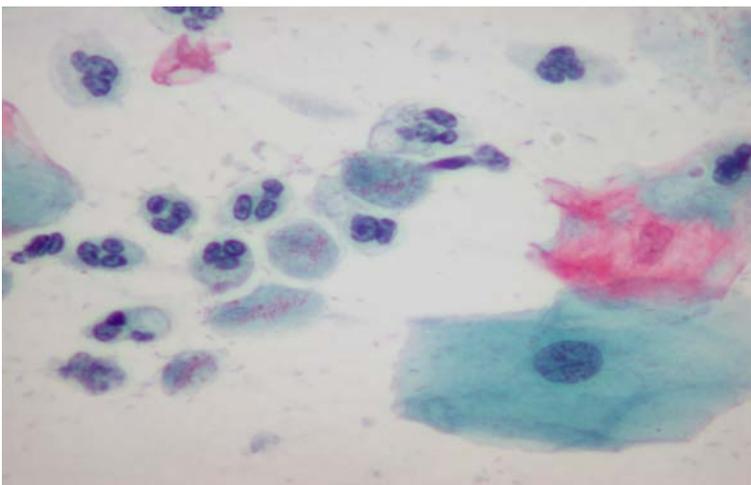

Fig.4.7. *Trichomonas vaginalis* organisms with intracytoplasmic eosinophilic granules. (Pap, x 400).

4. Malakoplakia is a rare chronic granulomatous inflammation of the urinary tract. Macrophages with characteristic intracytoplasmic, round Michealis-Gutmann bodies may be seen in urine sediments. (Fig.4.8).

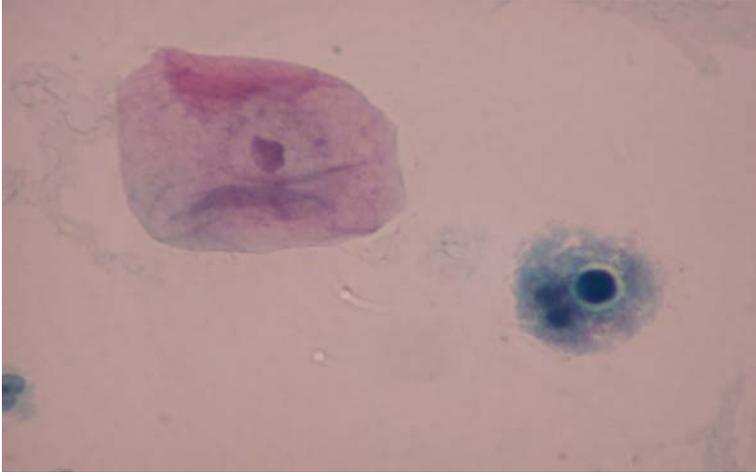

Fig.4.8. A macrophage with Michealis-Gutmann inclusion. (Pap, x 400).

5. Lithiasis. Lithiasis in urinary tract causes increased exfoliation of urothelial cells by mechanical trauma. The exfoliated cells are seen singly, in clusters and sheets. Cellular atypia may be present and requires careful evaluation. Bladder inflammatory ulcer caused by lithiasis may result in urothelial reparative process that exfoliates repair urothelial cells. (Fig.4.9). In a study of voided urine samples in patients with urinary lithiasis, Highmann and Wilson have found that in over 52.6% of cases no cytologic changes were noted. In 40.9% of cases the exfoliated cells were present in round clusters with smooth-bordered contours as seen in instrumentation artifacts. (Fig. 4. 4). Cytologic atypia was noted in 6.5% of cases, and in some cases an urothelial carcinoma cannot be ruled out on morphologic basis alone. As lithiasis and carcinoma may coexist in the urinary tract, follow-up is needed after stones are removed.

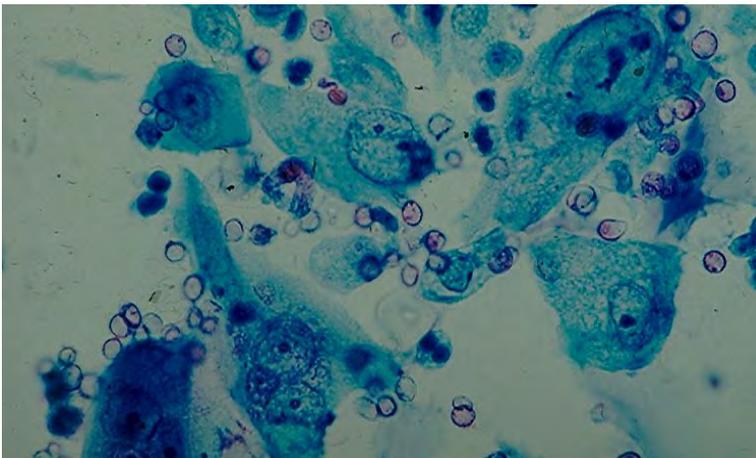

Fig.4.9. Reactive/repair urothelial cells with conspicuous nucleoli from a patient with bladder lithiasis. (Pap, x 500). Courtesy of Dr. G. B. Schumann, Hartford, CT, USA.

6. Radiation-induced cellular changes. Cellular changes in urothelium secondary to radiation may be observed in patients who have received pelvic radiation. The affected cells are seen singly and in clusters and a cellular enlargement with maintained N/C ratio is observed. The nuclei are generally pale but can be hyperchromatic and cytoplasmic vacuolization, multinucleation and prominent nucleoli may be present.

7. Chemotherapy-induced cellular changes.

- *Cyclophosphamide* may produce cellular changes as seen in cells with radiation-induced changes. The changes may be so marked that the affected cells may mimic cancer cells. As bladder carcinoma may occur in patients on long-term therapy with cyclophosphamide, these patients should be monitored by urine cytology at the beginning of the treatment.

- *Bisulfan* may produce urothelial cell atypia.

- *Thiotepa*, *Mitomycin C* and *adriamycin* are used as topical chemotherapeutic agents for treating superficial urothelial carcinoma. They may also produce cellular atypias, but the cellular changes are less severe as seen in patients treated with cyclophosphamide.

8. Immunotherapy with BCG may produce mild urothelial atypia and formation of granulomas in the bladder mucosa that may exfoliate epithelioid cells with carrot-shaped nuclei. (Fig.4.10).

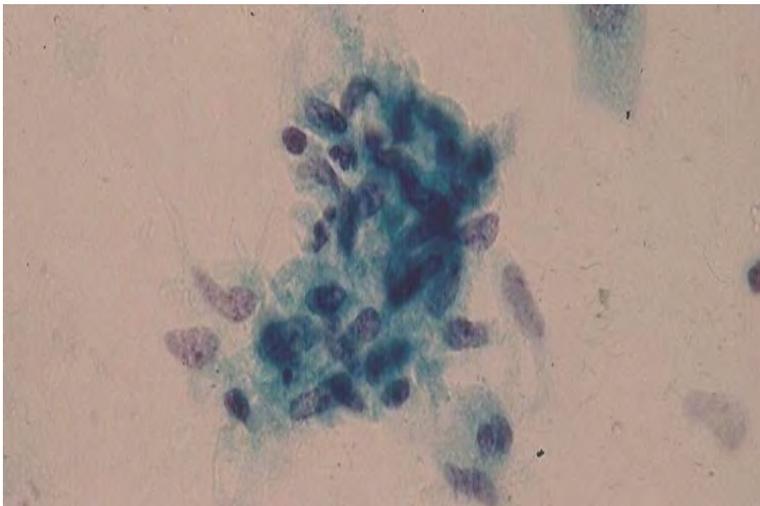

Fig.4.10. A cluster of epithelioid cells. (Pap, x 500).

UROTHELIAL NEOPLASMS

Urothelial (Transitional cell) carcinoma is the most common type of cancer arising from the urothelial lining of the urinary tract, with over 68,800 new cases expected to be diagnosed in 2008 in the United States. It is more common in men than in women, especially in patients over 50 years of age. Well-documented risk factors include occupational exposure to some

chemical compounds used in dye, leather, paint, organic chemical and rubber industries, *Schistosoma hematobium* infection, smoking, paralysis...Urothelial carcinomas arising from the renal pelvis and ureter are uncommon and account for about 5% of all urothelial carcinomas.

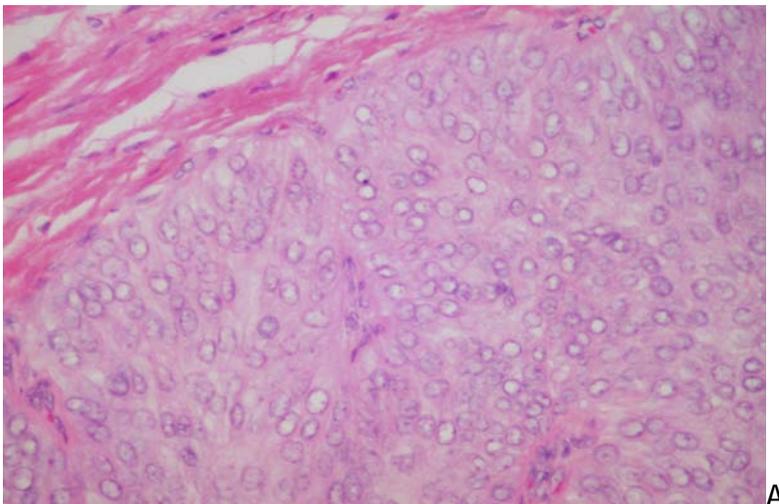

The World Health Organization (WHO)/International Society of Urologic Pathology (ISUP) classification system now is widely accepted as the standard one. In this WHO/ISUP classification system urothelial neoplasms are classified as follows:

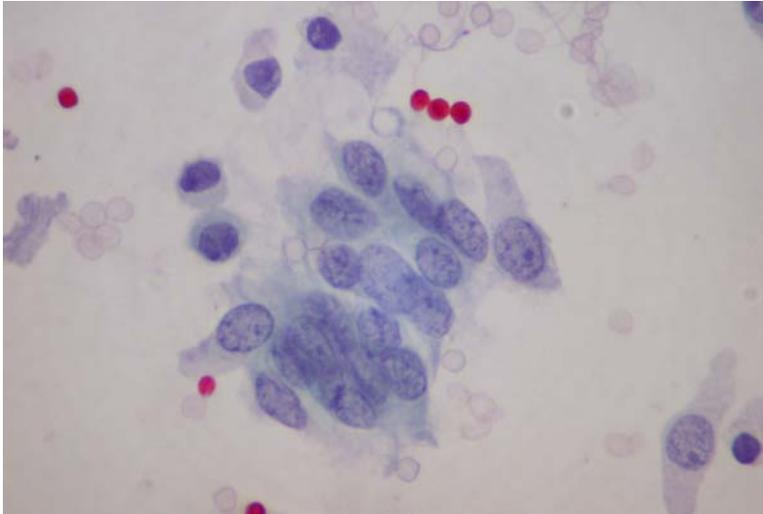

Table 1: Classification of Urothelial Neoplasms:

- Flat lesions with atypia:
 - . Dysplasia
 - . Carcinoma in situ
- Papillary lesions:
 - . Papilloma
 - . Papillary urothelial neoplasm of low malignant potential (Grade I papillary transitional cell carcinoma (TCC) in the old WHO classification).
 - . Low-grade urothelial carcinoma (Grade II TCC in the old WHO classification).
 - . High-grade urothelial carcinoma (Grade III TCC in the old WHO classification).

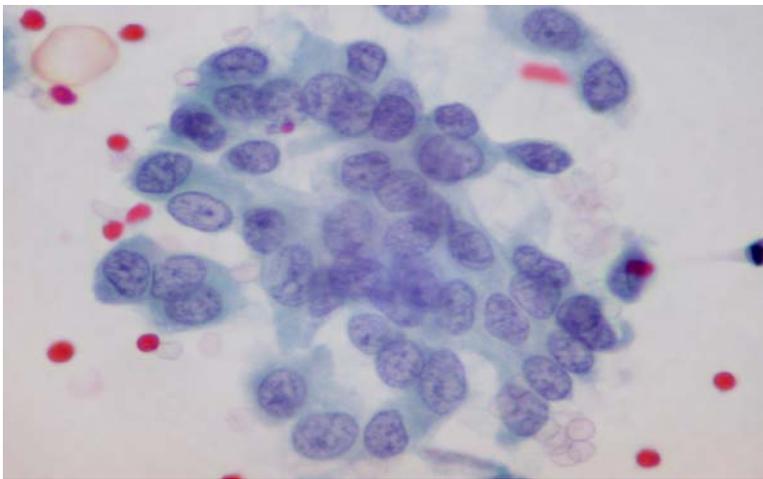

Urothelial dysplasia is a poorly defined lesion and its histologic diagnosis is subjective and irreproducible. Its cytologic manifestations in urine have not been defined.

Urothelial papilloma and Papillary urothelial neoplasm of low malignant potential can not be diagnosed by urine cytology as their tumor cells are identical to those of normal intermediate urothelium and to urothelial cells with minimal nuclear atypia. The tumor cells are seen singly and in small urothelial fragments with ragged cytoplasmic borders. A slight degree of irregularity of nuclear contours and inconspicuous nucleoli may be observed. (Fig. 4.11 and Fig. 4.12).

B

C

Fig. 4.11. Papillary urothelial neoplasm of low malignant potential:
A. Histology of tumor epithelium. (HE, x 200).
B & C. Small fragments of urothelium with ragged cytoplasmic borders and minimal nuclear atypia in bladder washing. (Pap, x 400).

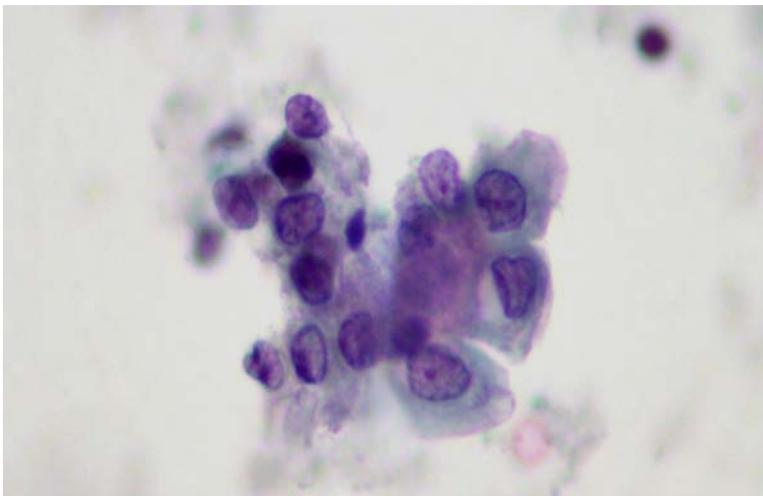

Fig. 4.12. Papillary urothelial tumor of low malignant potential showing in bladder washing a minute urothelial fragment displaying minimally atypical nuclei with or without inconspicuous nucleoli. (Pap, 400).

Low-grade urothelial carcinoma is a papillary neoplasm. Its incidence is 5 cases per 100,000 individuals per year and its mean age of occurrence is 69.2 years. The lesion is usually diploid and located on the posterior or lateral walls of the bladder. The tumor progresses to invasion and cancer death in < 5% of cases and 48-71% of the patients will develop tumor recurrence. Low-grade urothelial carcinoma is difficult to identify cytologically. The presence of irregular syncytial clusters of urothelial cells with ragged cytoplasmic borders or single atypical urothelial cells with enlarged, angulated hyperchromatic nuclei, high N/C ratio and cytoplasmic homogeneity have been used as diagnostic criteria for diagnosing low-grade urothelial carcinoma (transitional cell carcinoma, grade II according to the previous WHO classification) by some investigators, but these cellular changes do not constitute highly reliable criteria for identification of this type of neoplasm, as similar findings may be observed in urine sediments of individuals with no histologically confirmed urothelial carcinoma. (Fig. 4.13 and Fig. 4.14).

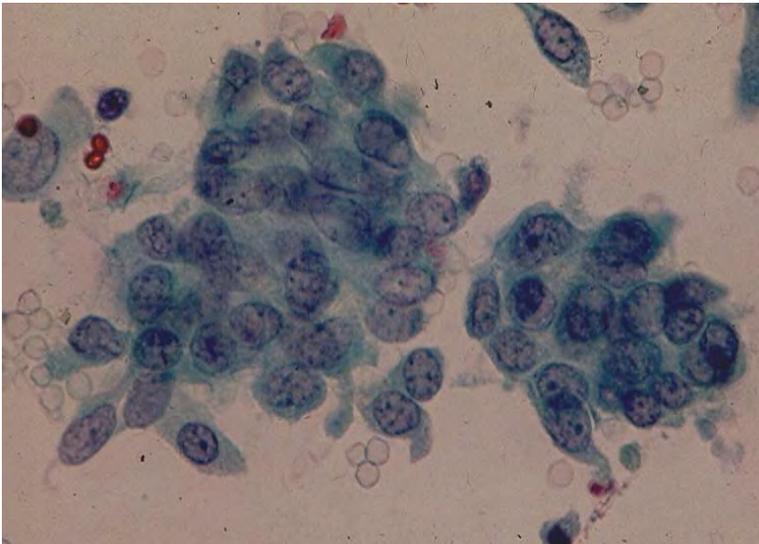

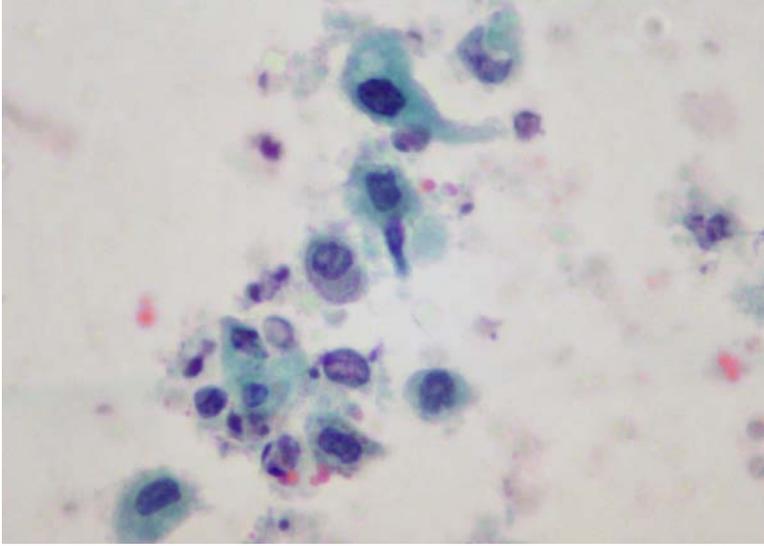

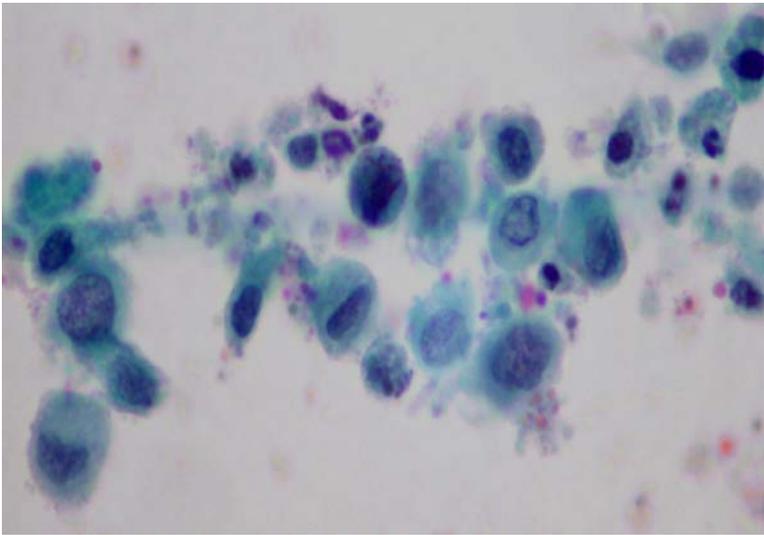

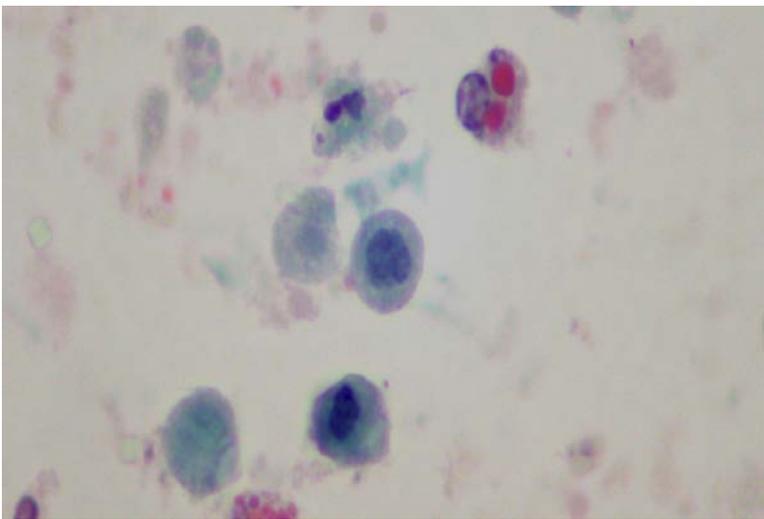

Fig.4.13. Low-grade papillary urothelial carcinoma showing in bladder washing two syncytial clusters of tumor cells with ragged cytoplasmic borders and oval, slightly hyperchromatic nuclei, inconspicuous nucleoli and a loss of nuclear polarity. (Pap, x 500).

B

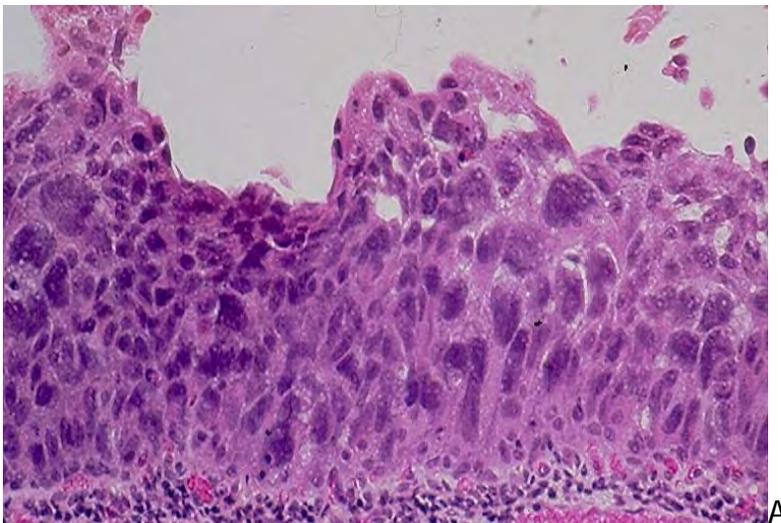

C

Fig. 4.14. Low-grade papillary urothelial carcinoma showing in voided urine isolated tumor cells with hyperchromatic nuclei and high N/C ratio. Two intracytoplasmic eosinophilic inclusions are noted in a degenerated urothelial cell in C. (Pap: A-C, x 400).

High-grade urothelial carcinoma and Carcinoma in situ. High-grade urothelial carcinoma is either papillary, nodular, or both and is often invasive. It accounts for at least 50% of all urothelial neoplasms and responsible for disease-related death in over 65% of cases. Carcinoma in situ is a flat, non-invasive neoplasm and usually found in urinary bladder harboring a high-grade urothelial carcinoma. The lesion is rarely seen in urinary bladder with a low-grade papillary neoplasm. It rarely occurs as a primary lesion, in <1% of patients with urinary symptoms of cystitis.

Both carcinoma in situ and high-grade urothelial carcinoma are aneuploid and composed of similar tumor cells with enlarged, hyperchromatic oval nuclei with irregular nuclear contours. Prominent nucleoli are present in almost all high-grade cancers, and may be present in carcinoma in situ. (Fig.4.15).

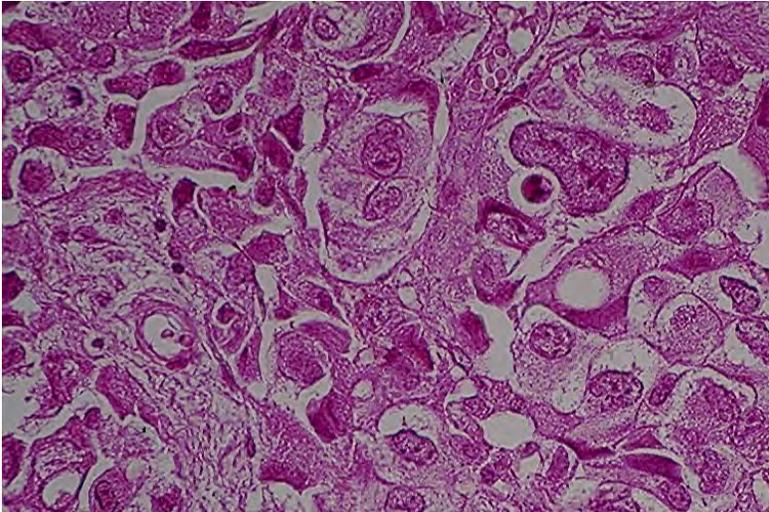

Fig.4.15. A: Histology of urothelial carcinoma in situ. (HE, x 200).
 B: Histology of high-grade urothelial carcinoma. (HE, x 200).

These two lesions have established cytodiagnostic criteria:

- malignant epithelial cells present singly and in loose clusters.
- tumor cells showing a high N/C ratio, marked nuclear hyperchromasia, coarsely granular chromatin, irregular nuclear contours and prominent nucleoli. (Fig. 4.16 and Fig. 4.17).

In contrast to invasive high-grade urothelial carcinoma, necrotic debris and inflammatory exudates are not seen in the smear background of carcinoma in situ cases. As these two lesions may co-exist in the same urinary bladder, it is not important to separate them cytologically. The patient will undergo a cystoscopic evaluation with tissue biopsy for confirmation before a treatment is initiated. As high-grade urothelial carcinomas commonly show focal areas with squamous and glandular differentiations, malignant squamous or glandular cells are not uncommonly found in urine sediments of patients with these high-grade neoplasms.

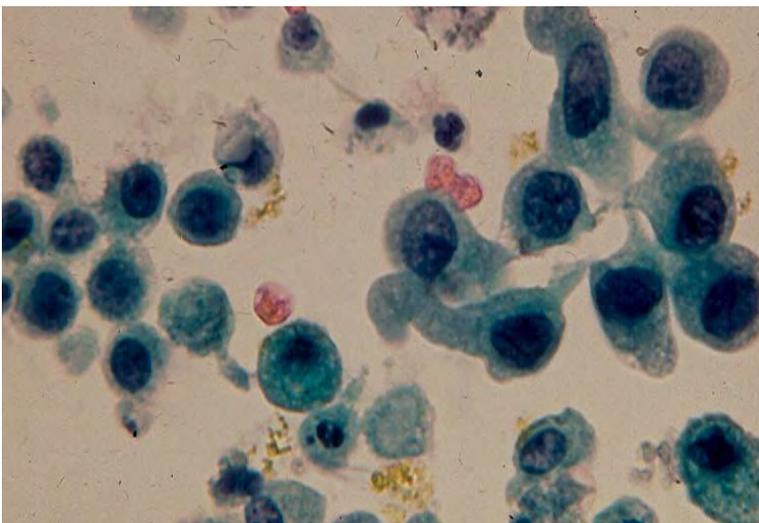

Fig. 4.16. Single malignant cells with enlarged, hyperchromatic nuclei, well-defined, basophylic cytoplasm from a case of urothelial carcinoma in situ. (Pap, x 500).

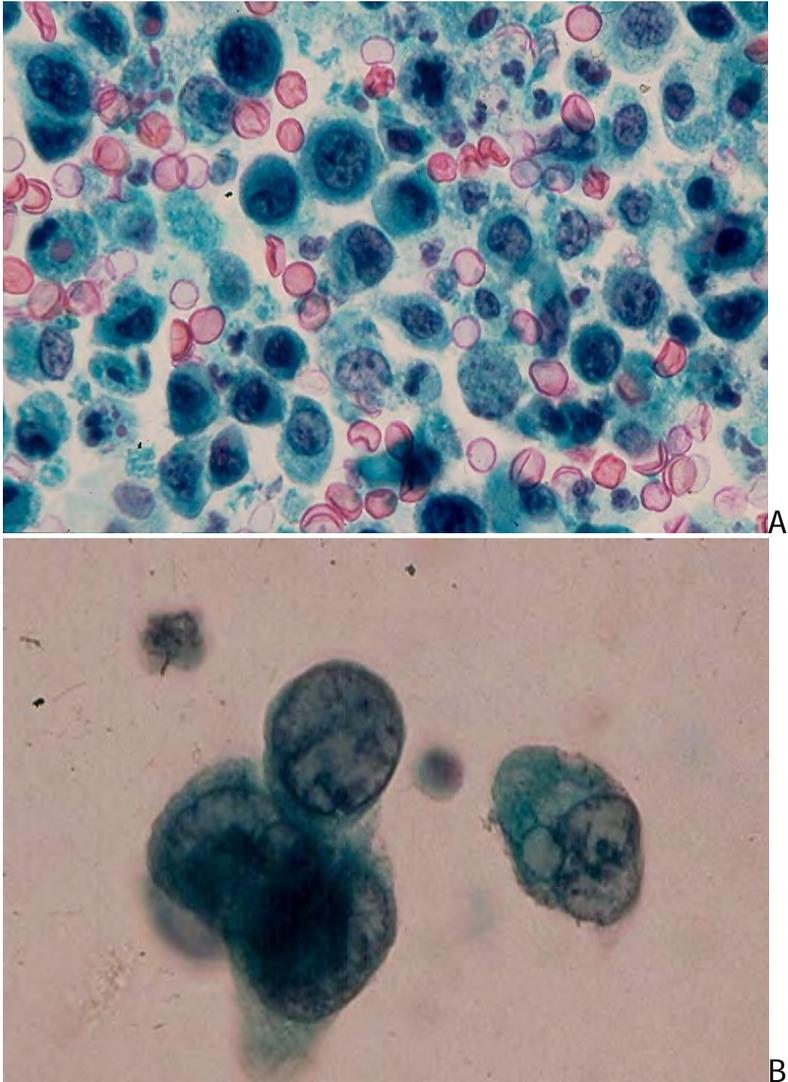

Fig.4.17. High-grade urothelial carcinoma of the bladder showing:
A: Numerous single pleomorphic malignant cells with prominent nucleoli.
B: Four large malignant epithelial cells with hypochromatic nuclei with irregular nuclear contours and prominent nucleoli. (Pap, x 500).

Sarcomatous urothelial carcinoma, a morphologic variant of high-grade urothelial carcinoma, is rarely encountered in practice. It yields in urine single spindle malignant cells with prominent nucleoli and scant, wispy cytoplasm. (Fig.4.18).

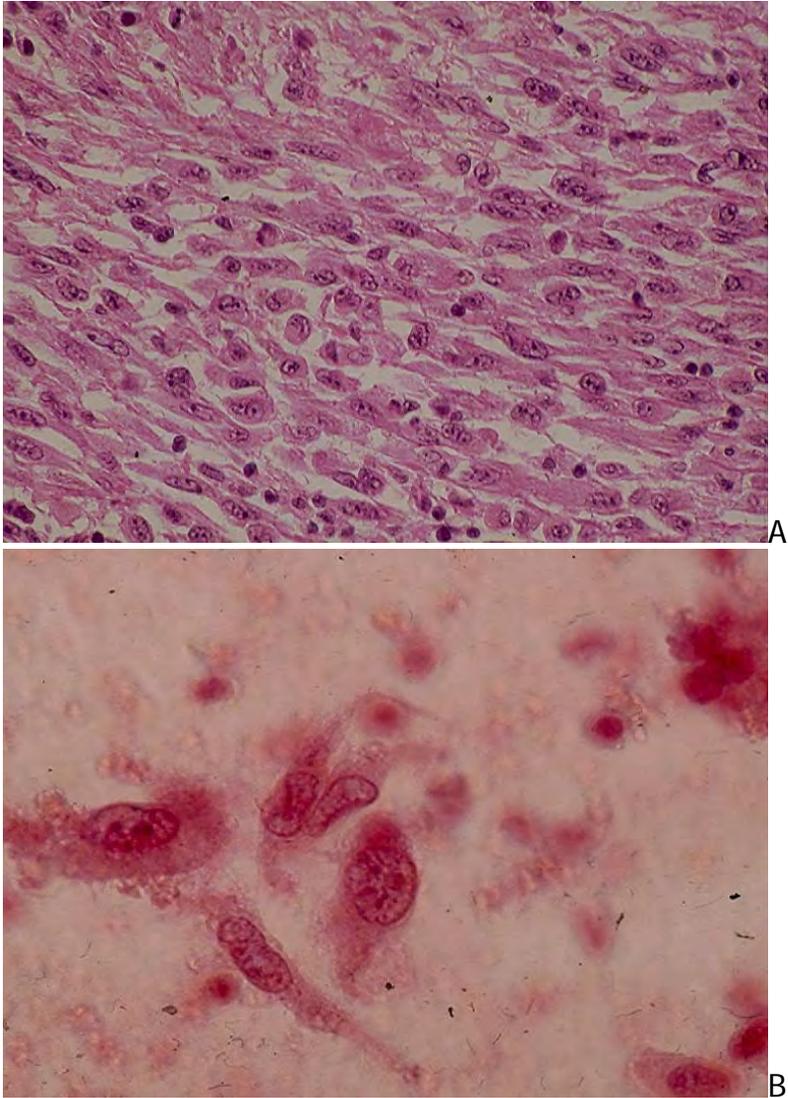

Fig.4.18. Bladder sarcomatoid urothelial carcinoma:

A: Tumor consisting of spindle cells with prominent nucleoli. (HE, x 200).

B: Urine showing isolated malignant spindle tumor cells with prominent single or double nucleoli and wispy cytoplasm. (Pap, x500).

OTHER TUMORS

Squamous cell carcinoma is usually well-differentiated and commonly seen in patients with *Schistosoma hematobium* cystitis. It is a rare neoplasm in the United States and accounts for about 3% of all primary bladder cancers. Cytologically, it is characterized by single and clustered malignant keratinizing squamous cells with angulated and hyperchromatic nuclei. (Fig.4.19).

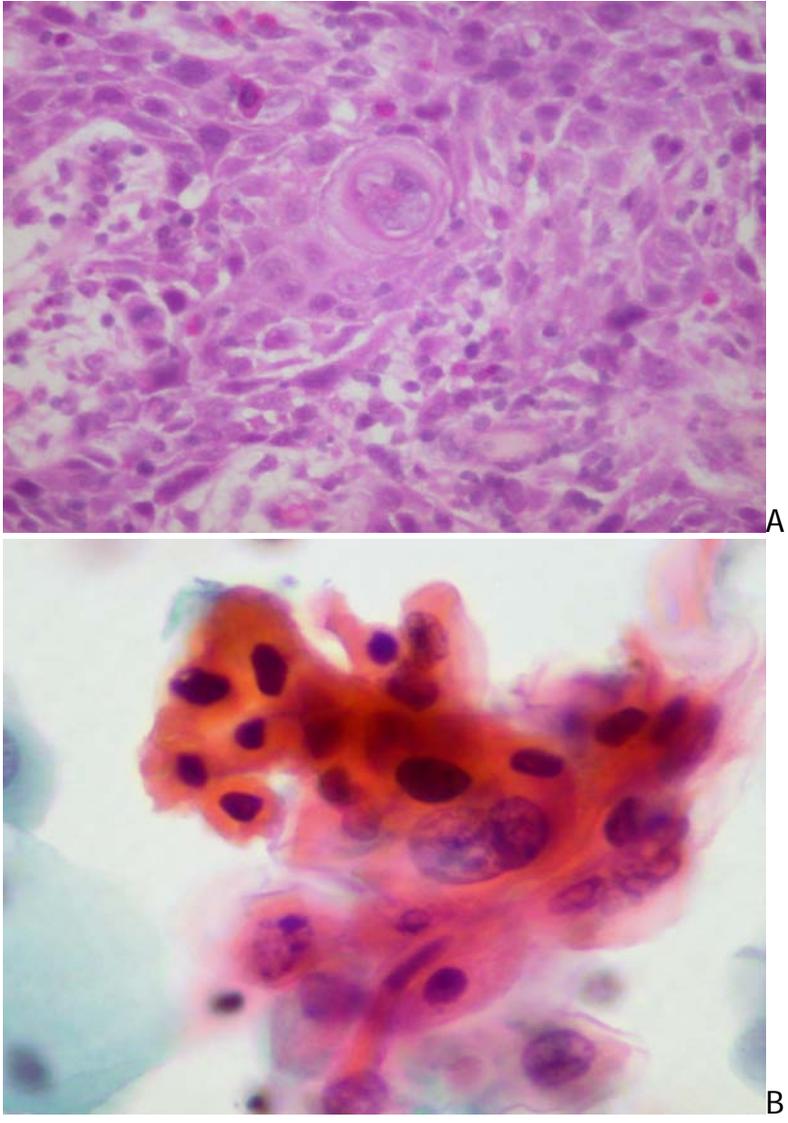

Fig.4.19. Bladder well-differentiated squamous cell carcinoma:

A. Histology of the tumor. (HE, x 200).

B. Keratinizing squamous cells with hyperchromatic, angulated or oval nuclei in voided urine. (Pap, x 400).

Verrucous squamous cell carcinoma is a rare variant of squamous cell carcinoma, accounting for 3-4.6% of bladder squamous cell carcinomas in patients with Schistosomiasis cystitis. It is rare in non-endemic areas. Verrucous carcinoma in patients with long-standing anogenital condyloma acuminata and bladder condyloma acuminatum may be related to HPV infection. The tumor exfoliates in urine abundant benign appearing squamous cells. (Fig.4.20)

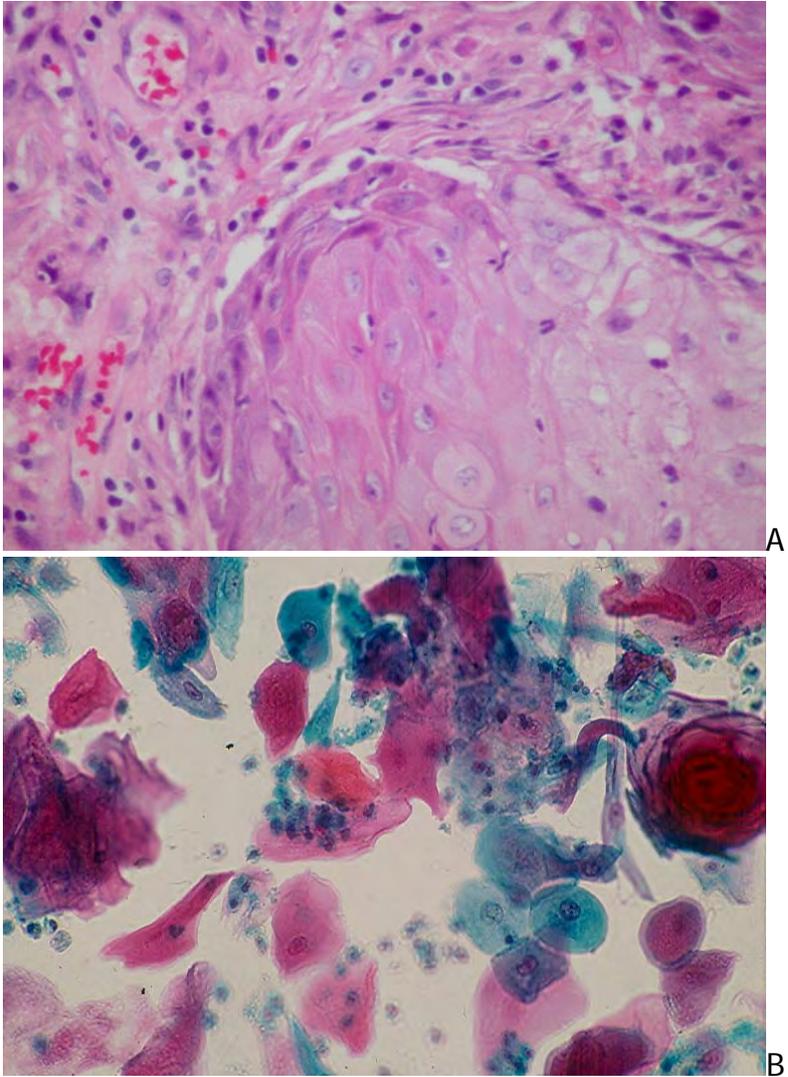

Fig.4.20. Bladder verrucous squamous cell carcinoma:
A. Histology of the tumor. (HE, x 200)
B. Urine showing abundant benign-appearing squamous cells. (Pap, x 200).

Adenocarcinoma accounts for about 2% of all bladder cancers. It occurs most commonly in patients with bladder exstrophy and is usually of intestinal type. A well-differentiated adenocarcinoma exfoliates in urine single and clustered malignant glandular cells with prominent nucleoli (Fig.4.21). Signet-ring malignant cells with prominent nucleoli may be seen in patients with a poorly differentiated tumor.

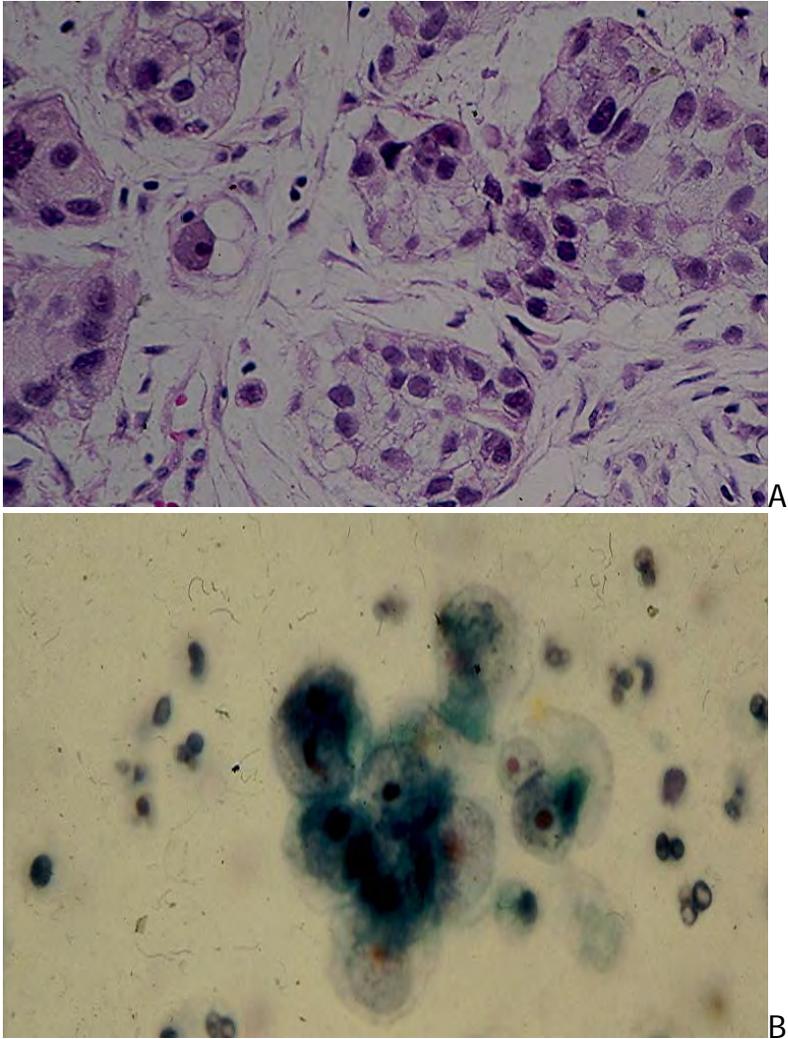

Fig.4.21. Well-differentiated adenocarcinoma, intestinal type:
A. Histology of the tumor. (HE, x 200).
B: Urine showing clustered malignant epithelial cells with clear, vacuolated cytoplasm and prominent, eosinophilic nucleoli. (Pap, x 500).

Small cell carcinoma is a very rare and aggressive tumor of the urinary tract. It shows in urine single and clustered malignant small cells with scant cytoplasm, hyperchromatic nuclei with "salt and pepper" chromatin. (Fig. 4.22). Nuclear molding may be seen in some tumor cell clusters.

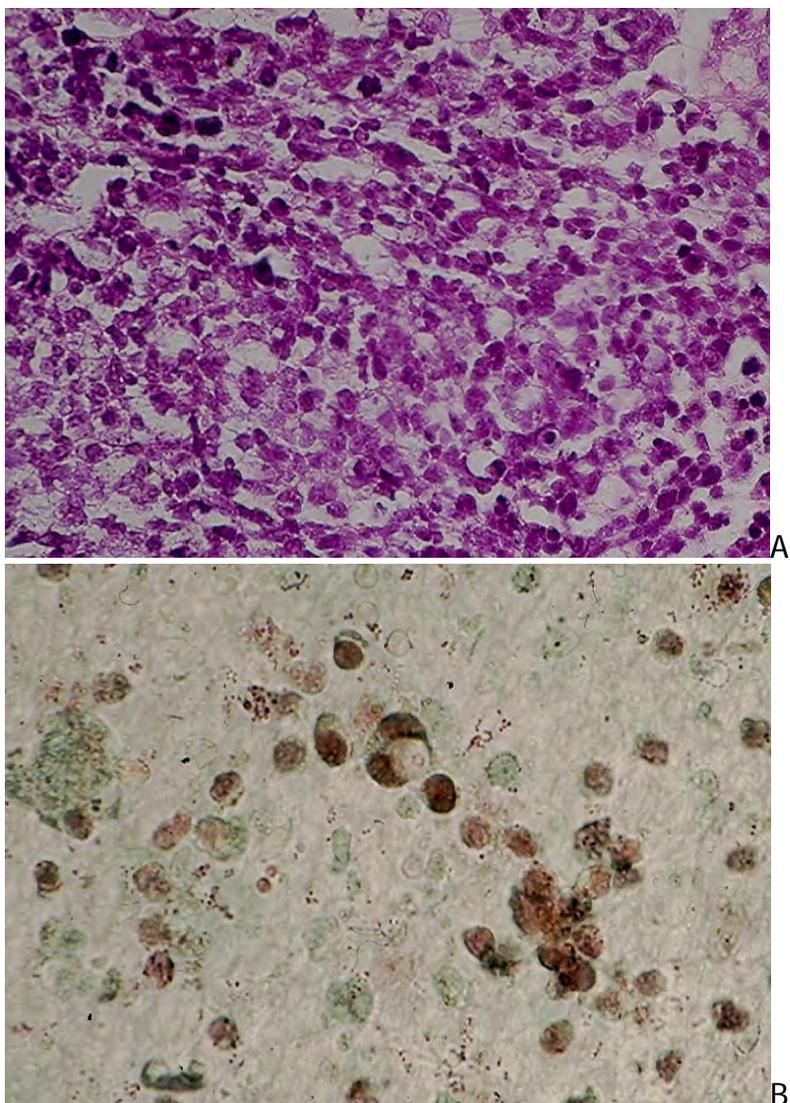

Fig.4. 22. Small cell carcinoma of the bladder:

A: Histology of the tumor. (HE, x 200).

B: Urine showing small malignant cells with small, round, hyperchromatic nuclei and necrotic debris. (Pap, x 500).

Renal cell carcinoma consists of 3 main histologic types: conventional or clear cell, papillary and chromophobe carcinomas. The tumor may invade the renal pelvis and exfoliates its cells in urine. The neoplastic cells usually occur in clusters and show a clear or granular cytoplasm and prominent nucleoli. (Fig.4.23). *Sarcomatoid renal cell carcinoma is a rare histologic variant*. It may exist in pure histologic form or as a component of a conventional renal cell carcinoma. The tumor shows in urine spindle malignant cells that are present predominantly singly. Immunocytochemical staining of the tumor cells with CK7, CK20, p63 and renal cell carcinoma antibodies is necessary to differentiate them from those of a sarcomatoid urothelial carcinoma.

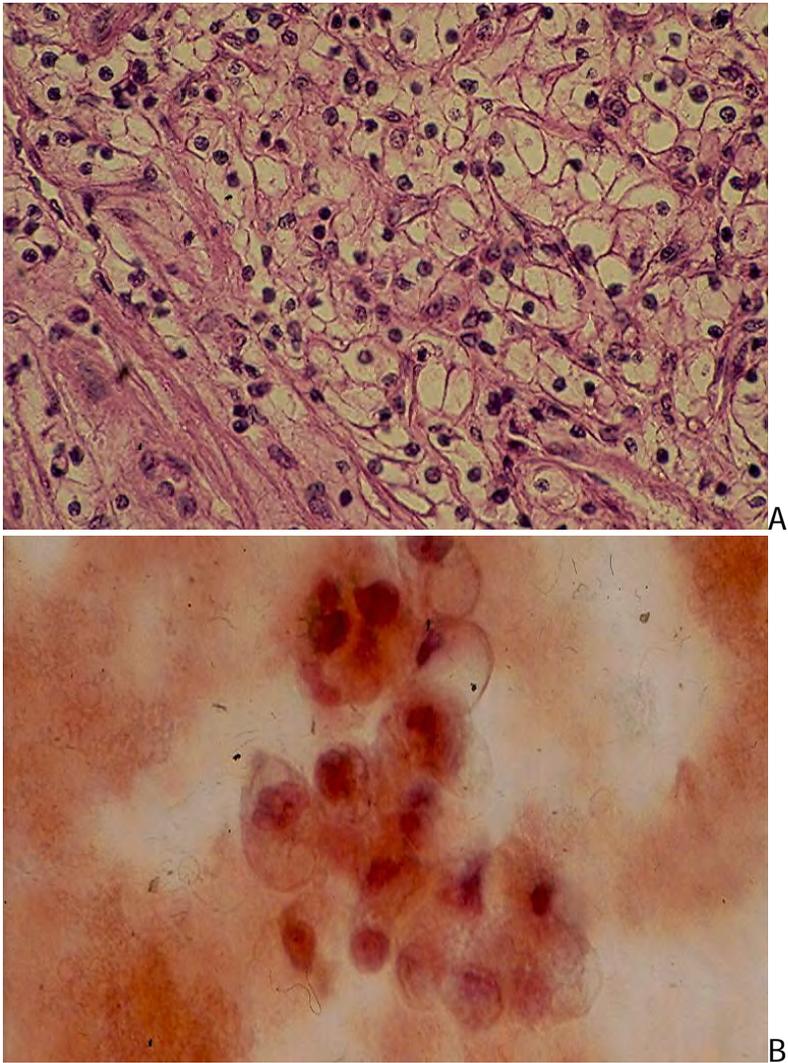

Fig.4.23. Renal cell carcinoma (RCC):

A: Histology of a conventional or clear cell RCC, grade I nuclei. (HE, x 200).

B: Bloody urine showing clustered tumor cells with clear cytoplasm, round or irregular nuclei and inconspicuous nucleoli. (Pap, x 500).

Renal collecting duct carcinoma is an uncommon tumor. It yields in urine single and clustered small malignant glandular cells with granular cytoplasm, oval nuclei and conspicuous nucleoli. Tumor epithelial fragments may also be observed. (Fig.4.24). The tumor cell cytoplasm, as in renal cell carcinoma, expresses cytokeratin and vimentin.

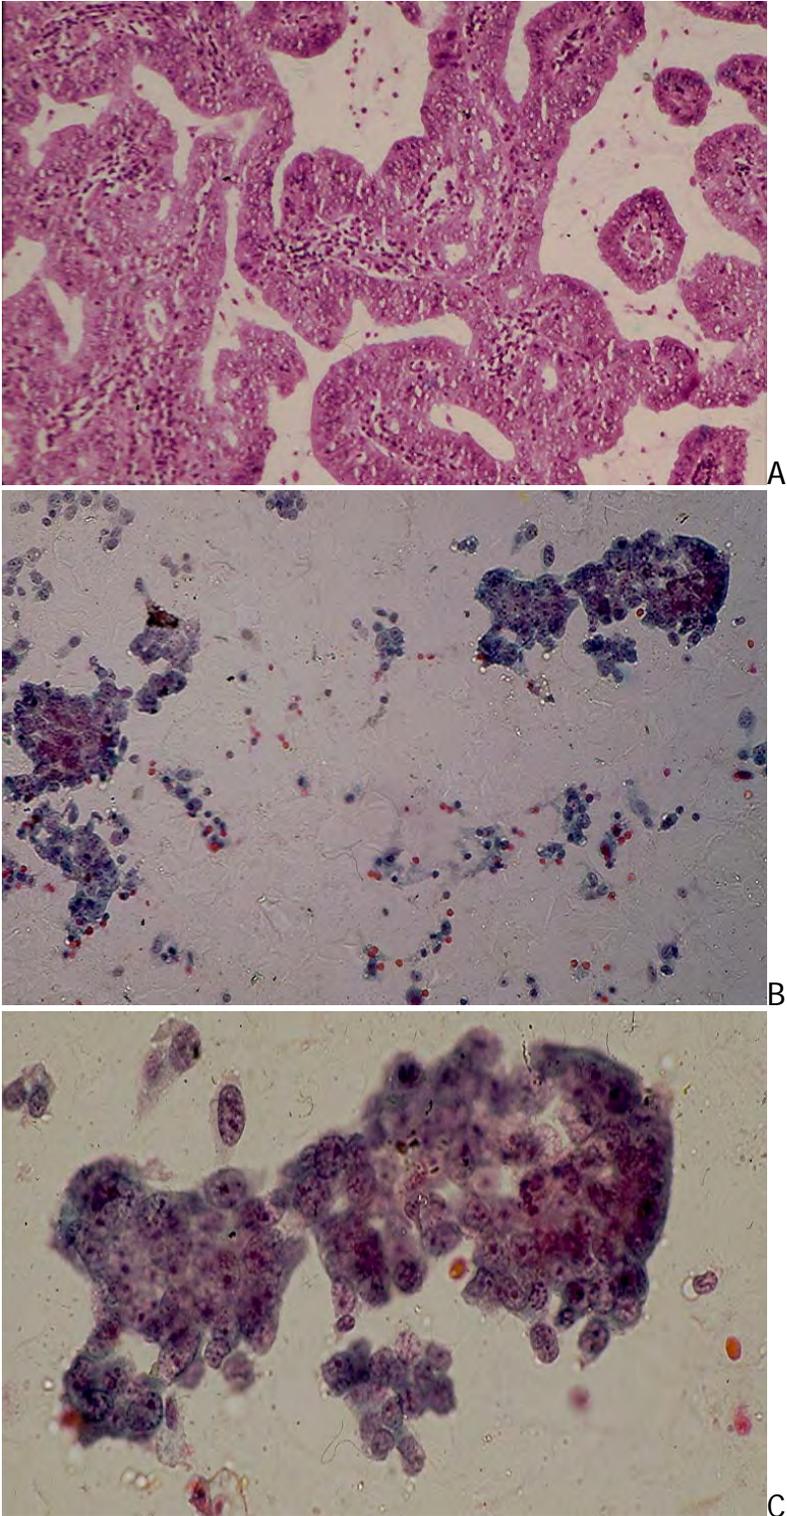

Fig.4.24. Renal collecting duct carcinoma.

A. Histology of the tumor. (HE, x 200).

B and C. Urine showing malignant glandular cells singly and in irregular epithelial fragments. Oval nuclei with prominent nucleoli are evident.

(Pap: B, x 200; C, x 500).

Prostatic adenocarcinoma invading the bladder base may exfoliate its cells in urine. The tumor is usually a high-grade adenocarcinoma that yields small clusters of malignant glandular cells with conspicuous nucleoli. (Fig.4.25). The tumor cell cytoplasm expresses prostatic specific antigen.

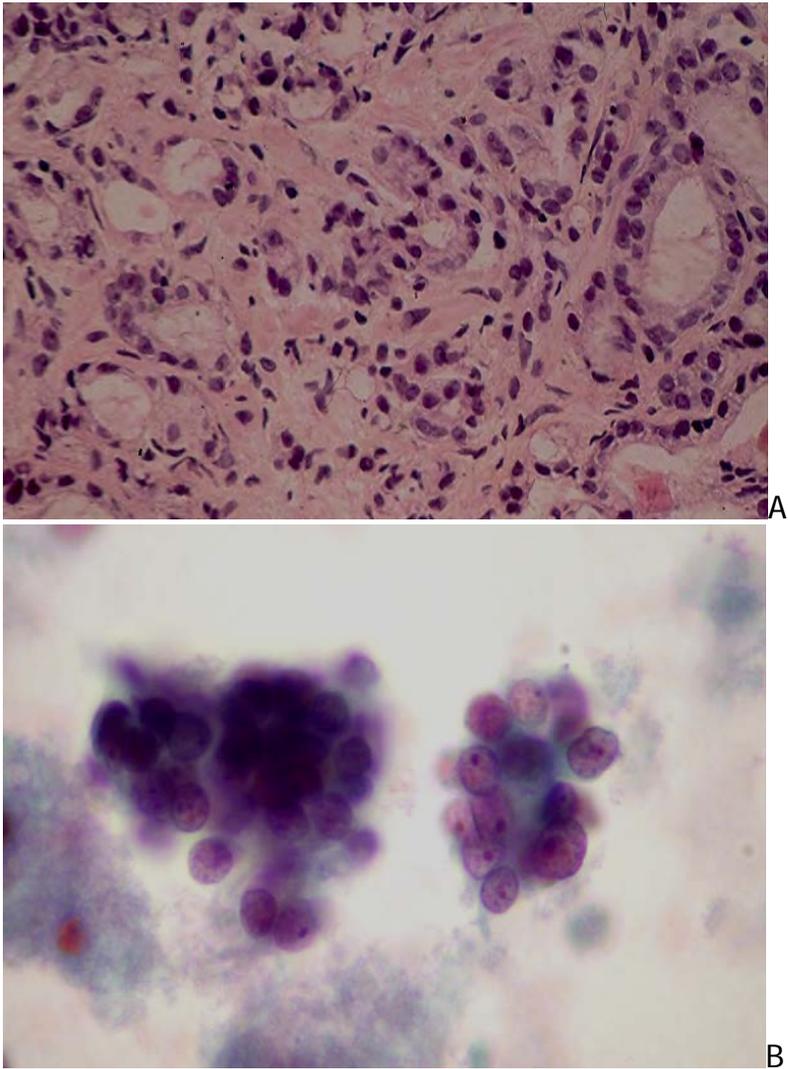

Fig.4.25. Prostatic adenocarcinoma:

A. Histology of the tumor. (HE, x 200).

B. Urine showing clustered malignant glandular cells with scant, clear cytoplasm and oval or round nuclei with prominent nucleoli. (Pap, x 500).

DIAGNOSTIC ACCURACY AND PITFALLS

Cyodiagnostic accuracy. Depending on the tumor grade, the diagnostic accuracy of urothelial carcinomas by urine cytology varies widely. For low-grade tumors a sensitivity and specificity rates of 30% and 80%, respectively, have been reported.

For carcinoma in situ and high-grade tumors the cyodiagnosis is almost always straightforward and has a sensitivity and specificity rates of 80% and 95%, respectively. Washing of ureter and renal pelvis was reported to have a sensitivity of 50% for high-grade tumors.

A number of *ancillary tests* have been developed to improve the cyodiagnostic accuracy of low-grade urothelial carcinoma and/or to determine the risk of tumor progression. These tests include flow cytometry and image analysis for aneuploidy determination, Bard bladder tumor antigen test, nuclear matrix protein NMP22 test, telomerase assays, microsatellite instability assays, hyaluronidase and hyaluronic acid assays, growth factors assays, cell adhesion molecules, fibrinogen degradation products assays, tumor-associated and blood group antigens and fluorescence in-situ hybridization (FISH). One multitarget FISH assay using a combination of centromeric probes with chromosomes 3, 7 and 17 with a locus-specific probe to band 9p21 was reported to have a sensitivity of 81% and a specificity of 96% for patients with urothelial cancer.

Diagnostic pitfalls may be encountered in urine cytology:

1- Degenerated urothelial cells: Urothelial cells lying in hypertonic urine may show remarkable degenerative changes. The cells become smaller and show pyknotic nuclei. A repeat examination of a freshly voided urine sample (taken after hydration) prepared without delay will be of diagnostic help in this case.

2- Endometrial cells: The presence of small hyperchromatic endometrial cells in a urine sample contaminated with menstruation may cause a diagnostic pitfall, as these cells may be mistaken for cancer cells. Therefore, the date of last menstrual period in a female patient should be provided by the physician who orders the test.

3- Instrumentation may produce cellular changes leading to misinterpretation. An indwelling bladder catheter may exfoliate tightly arranged atypical/reactive/repair urothelial cells mimicking cytologic findings in a low-grade urothelial carcinoma.

4- Infection, lithiasis, radiation and chemotherapy may also cause some cellular alterations (nuclear enlargement and hyperchromasia, conspicuous nucleoli) mimicking cells of a low-grade urothelial carcinoma.

5- *Repair renal tubular cells* may show severe cellular atypias, mimicking malignant glandular cells. The reader is referred to Chapter 5 for illustration of repair renal tubular cells.

6- *Washing samples of the ureter and renal pelvis* may be compounded with diagnostic errors, as normal urothelial cells at these two anatomic sites normally display larger and hyperchromatic nuclei, readily mistaken for malignant cells by an inexperienced observer. (Fig.4.26). The advantage is that the cell samples are usually bilateral and one of them is presumably benign, for comparison.

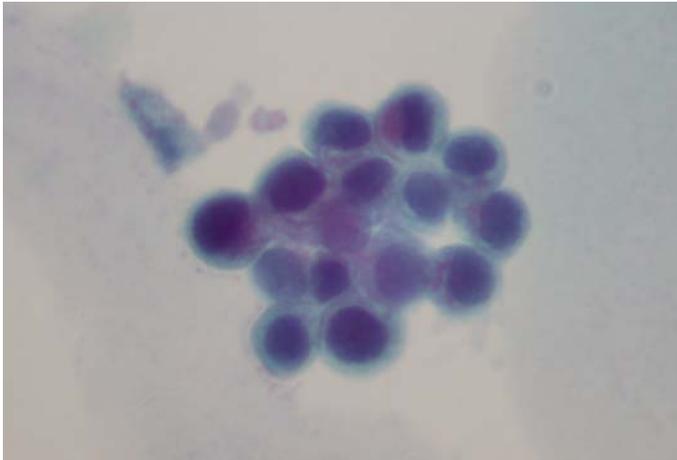

Fig.4.26. Ureteral washing showing a fragment of urothelium with enlarged, hyperchromatic nuclei and high nuclear: cytoplasmic ratio. (Pap, x 400).

Urine in Non-neoplastic Renal Parenchymal Diseases

Gia-Khanh Nguyen

Urinalysis has been the cornerstone in evaluating renal parenchymal diseases since the 19th century. It is traditionally performed by nephrologists who use a bright-field or phase-contrast microscope to evaluate wet and unfixed urine sediments. In this method of clinical investigation cells exfoliated from the renal parenchyma and lower urinary tract and non-cellular elements do not show well-defined microscopic features and the cell samples cannot be kept indefinitely for retrospective studies. Cytologic evaluation of fixed and stained urine sediments in the investigation of non-neoplastic lesions of the renal parenchyma is not routinely performed in diagnostic cytology, and reports on this topic have been rarely encountered in the literature. This chapter presents the cytologic findings in Papanicolaou-stained urine sediments in renal glomerular and tubular diseases.

COLLECTION AND PREPARATION OF CELL SAMPLES

To investigate non-neoplastic renal parenchymal diseases urine samples should be prepared according to the technique used for *semiquantitative cytologic urinalysis*. A sample of 100 to 200 mL of mid-stream, freshly voided urine without ethanol fixatives is immediately submitted to the hospital cytology laboratory for processing. An aliquot of 10 mL is centrifuged at 1800 rpm for 10 min. 9 mL of the supernatant is discarded, and 4 cytospin preparations or smears are prepared from the remaining 1 mL of the sediment by cytospin technique, with a centrifugation speed of 900 rpm. If the cell button is judged to be too thick, it is gently smeared with a thin coverslip. The smears obtained are immediately fixed in 95% ethanol for 5 minutes and then stained by the Papanicolaou method. All four smears are screened with a x10 objective and selected cellular areas are carefully evaluated at a higher magnification with a x40 objective. Different cellular elements and casts are evaluated and counted. G1 cells are defined as distorted red blood cells (RBC) with a doughnut-like shape, membranous protrusions or blebs and target configuration. Distorted RBCs without target configuration, doughnut-like shape and membranous blebs or protrusions are collectively grouped with morphologically normal RBCs as "RBCs". A G1 cell: total RBC ratio is calculated by evaluating 200 RBCs including G1 cells.

NORMAL URINE

In healthy individuals 0-2 renal tubular cells, 3-5 RBCs and 3-5 polymorphonuclear leukocytes are present in each high-power field. Rare hyaline or granular casts may be observed. (Fig.5.1). There are, in addition, a variable number of urothelial and squamous cells. Proximal convoluted tubular cells are cuboidal in shape, measure 20-60 microns in greatest dimension and have a well-defined, coarsely granular cytoplasm and slightly eccentrically located, single, oval nuclei. Distal convoluted tubular cells are smaller, measure 12-20 microns in greatest dimension and have a well-defined, finely granular cytoplasm and centrally located, single, oval nuclei. Cells derived from collecting tubules are small and cuboidal in shape with well-defined granular cytoplasm and centrally located, single, round nuclei. Cells from the loops of Henle are rarely seen. These are smaller cuboidal cells with round nuclei and scant cytoplasm.

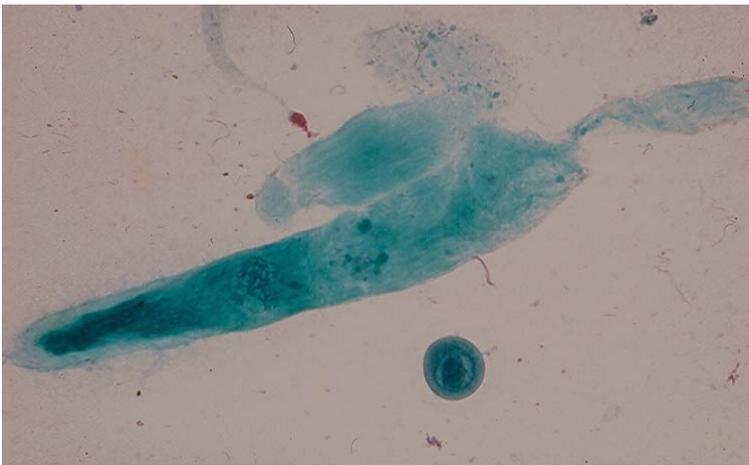

Fig.5.1. A hyaline cast (above) and a granular cast (below) in normal urine. (Pap, x400).

RENAL GLOMERULAR DISEASES

Microscopic hematuria is a common clinical problem and has numerous etiologies, including renal glomerular and tubular diseases, urolithiasis, renal tumor, urothelial neoplasm, infection of the kidney and lower urinary tract and rupture of suburothelial capillary blood vessels. Since the clinical investigation of microscopic hematuria is costly, time-consuming and inconvenient to the patient, identification of patients with glomerular bleeding or lower urinary tract hematuria is desirable for further nephrologic or urologic investigation.

The most common manifestations of renal glomerular diseases are microscopic hematuria and proteinuria. Usually the presence of red blood cell (RBC) casts in urine sediments is regarded as an evidence of glomerular hematuria or disease. However,

38% of patients with histologically confirmed renal glomerulopathy in Nguyen's 2003 study showed only an increased number of RBCs and no identifiable RBC casts in their urine sediments.

Birch and Fairley were apparently the first investigators who reported that RBCs leaking from renal glomeruli were dysmorphic, in contrast to normal RBCs of non-glomerular origin. This finding proved to be of diagnostic value in some studies. However, other studies were unable to confirm the diagnostic value the above-mentioned observation. In 1992 Tomita et al. have reported that urinary RBCs with target configuration, doughnut-like shape and membranous protrusions or blebs or G1 cells constituted a reliable marker for renal glomerular hematuria. This finding was subsequently supported by the work of other investigators. The observation of Tomita and his associates was actually not original, as urinary RBCs with similar morphological changes had been previously observed in urine samples from patients with acute glomerulonephritis by Addis in 1948 and by Kohler et al. in 1991. The latter investigators had named those RBCs acanthocytes and found that an acanthocyte/total RBC ratio equal or greater than 5% was associated with a glomerulonephritis in over 50% of cases. This finding was supported by the work of Kitamoto et al. who found that a G1 cell/total RBC ratio greater than 5% was an evidence for glomerular bleeding/disease. Despite several studies conducted in the past two decades, morphologic criteria of dysmorphic RBCs had not been well-defined, and the required percentage of these cells for making a firm diagnosis of glomerular bleeding had not been uniformly agreed upon. The main reasons for the lack of well-defined morphologic criteria of dysmorphic RBCs were that in all of those studies unfixed urine sediments and bright-field and phase-contrast microscopes were used and that the wet-mounted slides could not be kept permanently for review. Because of the aforementioned reasons, there were significant discrepancies in observer interpretations of dysmorphic RBCs. The pathogenesis of dysmorphic RBCs is largely unknown. In two studies, RBCs leaking through diseased glomeruli were normal, and these cells acquired dysmorphic changes by osmotic injury while passing through hypotonic renal tubules and by exposure to a concentrated acidic urine. In another study the dysmorphic changes, in certain cases, could be attributed to 2 consecutive injuries: mechanical injury to the cell membrane during passage through damaged glomerular basement membranes and osmotic injuries during passage through hypotonic renal tubules. In the study conducted by Ye and Mao, a combination of a mechanical injury to the cell membrane, osmotic injury and exposure to acidic urine was suggested to be necessary to cause dysmorphic changes of RBCs.

The absence of G1 cells in urine sediments in patients with severe renal tubular injury has indicated that G1 cells could not be formed in the absence of a glomerulopathy, and this finding supported the work of Ye and Mao who have suggested that a mechanical injury to RBC membranes was needed, in addition to intratubular osmotic injuries, to produce dysmorphic changes of RBCs infiltrated through diseased renal glomeruli. G1 cells were not seen in renal tubular or lower urinary tract bleeding, according to Nguyen's 2008 study.

A G1/total RBC ratio varying from 10-100% indicates a renal glomerular bleeding. If G1 cells are not identified, at least 50% of renal glomerular diseases will be missed by urine cytology in patients with renal glomerular diseases showing no RBC casts in urine. In the absence of RBC casts the presence of G1 cells alone in urine sediments has correctly predicted the presence of a glomerular lesion in at least 86% of the cases, according to Nguyen's 2008 report.

As G1 cells are formed in acidic urine with high osmolarity, first morning urine samples are more suitable for detection of G1 cells. Random or spot urine that is often diluted and alkaline is less suitable for G1 cell detection, and diluted urine samples from patients with impaired renal function and from individuals with excessive water intake are suboptimal for G1 cell detection. Urine samples contaminated with vaginal secretion may obscure G1 cells. Therefore, perineum washing in women is required prior collection of voided urine samples for SCU. Urine collected by bladder catheterization is suboptimal for SCU as it contains abundant RBCs and urothelial cells. Faulty collection or preparation techniques are usually the main reasons for a false-negative result. Freshly voided urine without ethanol fixatives is the best sample for identifying G1 cells, as a long fixation in ethanol will destroy RBCs and RBC casts.

Effort should be made to identify pseudo-G1 cells that are artifactual changes and these cells are more commonly seen in important urinary tract bleedings of nonglomerular origin and they are not a marker of renal glomerular bleeding. Urine sediments containing pseudo-G1 cells always show only RBCs with target configuration that have a thick hemoglobin rim with outer and inner smooth contours and no membranous fragmentation and blebs or protrusion, as seen in G1 cells. (Fig.5.2). The morphogenesis of pseudo-G1 cells is unknown.

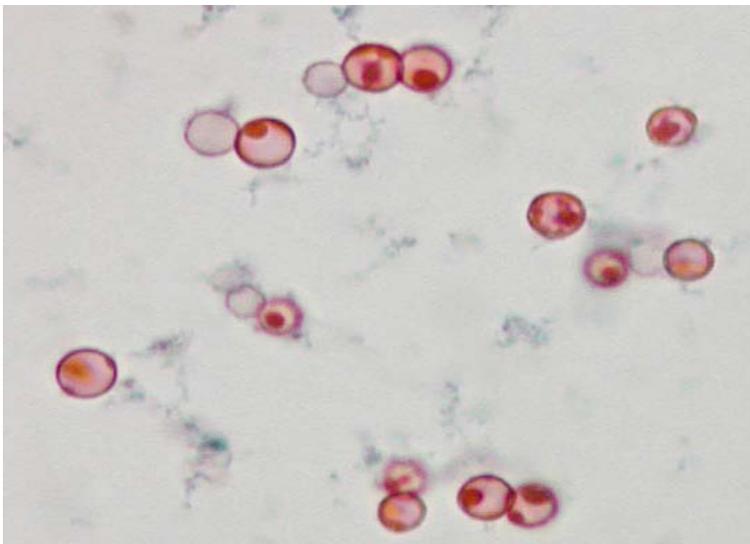

Fig. 5.2. Pseudo-G1 cells. (Pap, x 500).

CYTOLOGIC FINDINGS

In Nguyen's 2003 study of 178 patients with histologically confirmed renal glomerular diseases 4 smear patterns were identified, and each pattern was associated with different types of renal glomerular lesion/disease.

1. G1 Cells only: This pattern was the most common one and present in 54% of patients. (Fig.5.3).
2. G1 Cells and RBC Casts: This pattern was present in 20% of patients. (Fig. 5.4).
3. RBC Casts and No G1 Cells. This pattern was present in about 18% of patients.
4. Normal RBCs only. This finding was seen in less than 10% of patients.

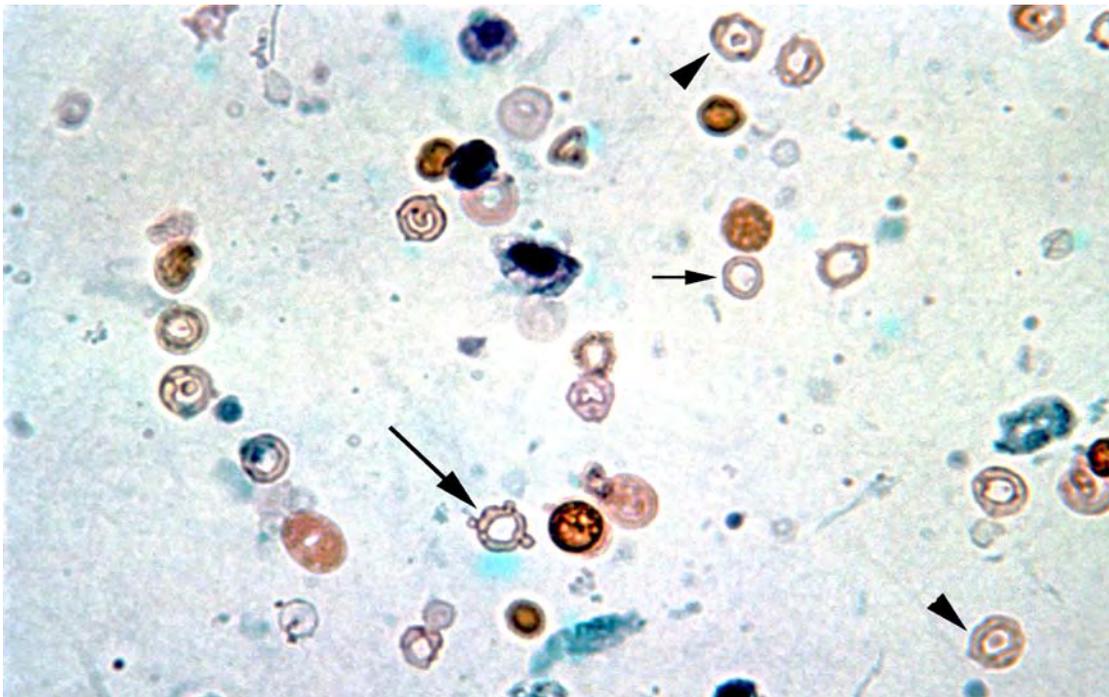

Fig.5.3. A. Numerous G1 cells in urine sediment of a patient with IgA nephropathy: G1 cell with target configuration (arrow head), G1 cell with doughnut-like shape (short arrow) and G1 cell with membranous blebs (long arrow). (Pap, x 800).

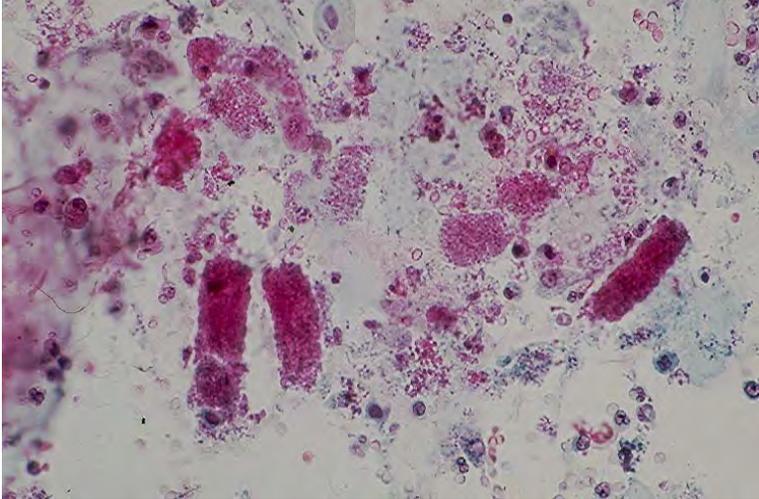

Fig. 5.4. Numerous RBCs including G1 cells and RBC casts. (Pap, x 100).

Patients with renal glomerular disease usually present with either a *nephritic syndrome* or nephritic syndrome.

Nephritic syndrome is characterized by the presence of numerous RBCs and RBC casts in urine sediment and it is commonly found in patients with acute glomerulonephritis, IgA nephropathy and rapidly progressive glomerulonephritis.

Nephrotic syndrome is usually present in patients with minimal change disease, focal glomerular sclerosis, membranous nephropathy and membranoproliferative glomerulonephritis. Some conditions such as HIV-associated nephropathy, systemic lupus erythematosus, Hepatitis C viral infection can be associated with either a nephrotic or nephritic syndrome. However, exceptions do exist. A nephrotic syndrome is characterized cytologically by the presence of renal tubular cells with large intracytoplasmic fat droplets, fatty casts, a few RBCs and no RBC casts. (Fig.5.5).

A. A cluster of renal tubular cells with intracytoplasmic fat droplets. (Pap, x 500).
B. A tubular fatty cast, a tubular epithelial cell (above) and a few polymorphonuclear leukocytes. (Pap, x 400).

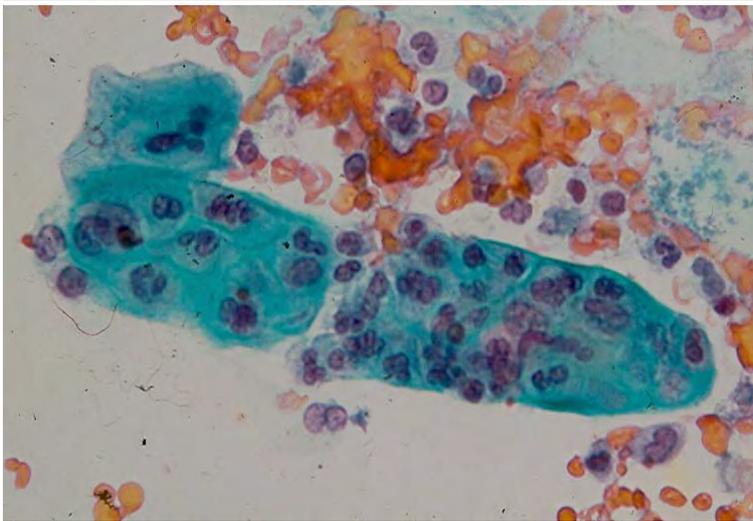

ACUTE TUBULOINTERSTITIAL NEPHRITIS

The disease has several etiologies including drug reaction (antibiotics, nonsteroid anti-inflammatory drugs, diuretics), systemic bacterial infection or viral infection. Most cases are drug related, and when no cause is found it is classified as idiopathic. Clinically the disease is most commonly characterized by fever, flank pain, microscopic hematuria and eosinophilia. The urine sediment shows numerous polymorphonuclear leukocytes, white blood cell casts, renal tubular cells and abundant or rare eosinophils that can be well-visualized by Wright stain. (Fig.5.6).

B. A RTC cast.
C. A white blood cell cast containing several polymorphonuclear leukocytes.
D. Several eosinophils.
(Pap: A, x 500; B, x 200; C and D, x 500).

CHRONIC TUBULOINTERSTITIAL NEPHRITIS

The main causes of this disease are obstructive uropathy, reflux nephropathy, heavy metal exposure (lead and cadmium) and prolonged ingestion of acetaminophen. It is characterized by a decreased urine output, metabolic hyperchloremic acidosis and hyperkalemia. The urine sediment shows a few thick broad hyaline/granular casts and a number of inflammatory cells. (Fig.5.7).

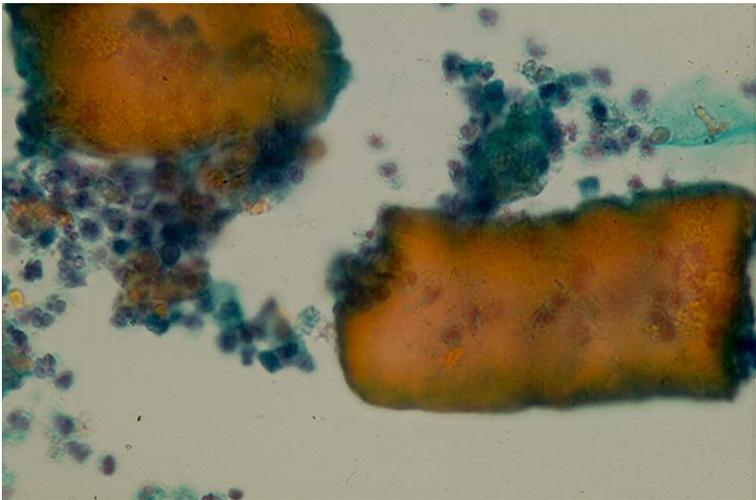

Fig. 5.7. Thick broad hyaline casts and polymorphonuclear leukocytes. (Pap, x 400).

ACUTE RENAL FAILURE

Acute renal failure (ARF) is characterized by a sudden increase of BUN and serum creatinin and oliguria. Polyuria is present in some cases. It is classified into 3 types: prerenal, post renal and renal.

1. Prerenal ARF is caused by poor renal perfusion of different reasons. The urine sediment is normal and shows only a few hyaline casts.
2. Postrenal ARF is caused by an obstruction of urinary tract by an urinary stone, enlarged prostate or cancer invasion obstructing the urine flow. The urine sediment is also normal in this case and some crystals may be observed.
3. Renal ARF is caused by intrinsic renal diseases such as acute tubular necrosis, acute glomerulonephritis and acute tubulointerstitial nephritis.

Acute tubular necrosis (ATN) is caused by hypotension and endogenous or exogenous nephrotoxins. It can be oliguric or polyuric. Endogenous nephrotoxins include myoglobin, crystals and Bence Jones proteins. Myoglobinuria is secondary to rhabdomyolysis that may

occur in patients with alcoholic abuse, crush injury, prolonged coma or seizures. The patients have a high serum CK level and hyperkalemia and show in urine sediments numerous myoglobin pigment casts, in addition to renal tubular cells (RTC), RTC casts and RBCs, and no G1 cells are identified. (Fig. 5.8).

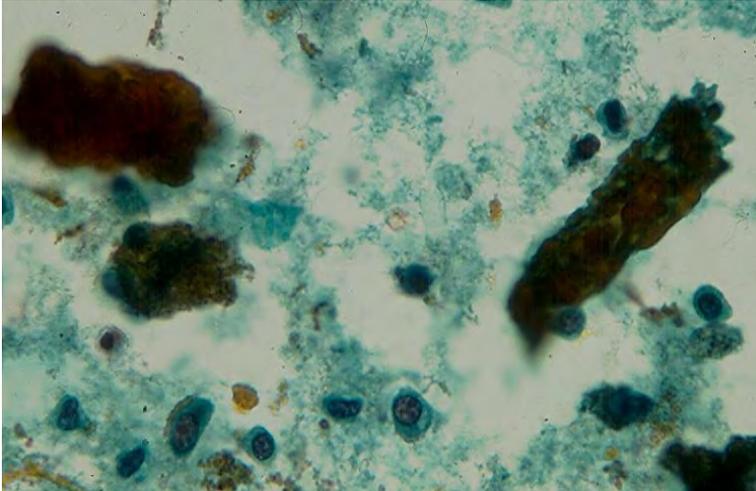

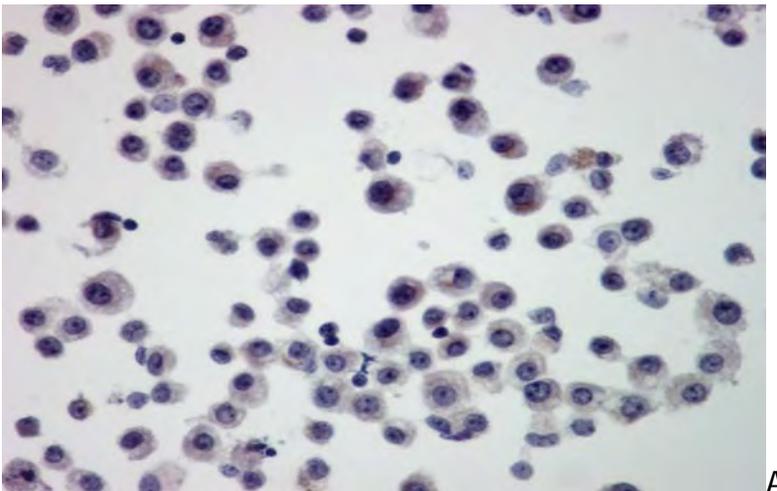

Fig.5.8. Dark brown myoglobin casts and single renal tubular cells are present. (Pap, x400).

Uric acid crystals are seen in patients with hyperuremia secondary to chemotherapy for leukemia, lymphoma and some solid cancers. Bence Jones proteins are detected in patients with multiple myeloma. Exogenous nephrotoxins include antibiotics, radiographic contrast material and cyclosporine. Antibiotics include gentamycin, tobramycin and amikacin. Aminoglycoside-induced ATN is nonoliguric. An ATN is characterized by the presence of numerous RTCs and a few RTC casts in urine sediments. RBC casts may be seen if a severe tubular bleeding is present but no G1 cells are identified. The RTCs stain positively with vimentin antibody while other benign epithelial cells in urine do not. (Fig.5.9).

A

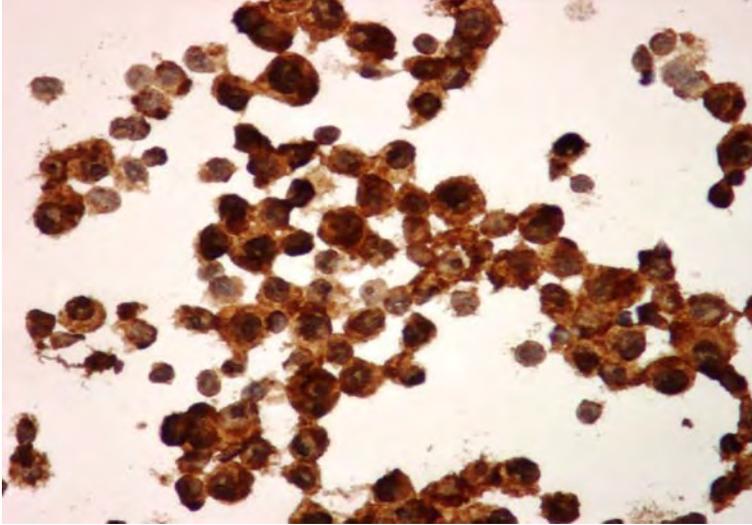

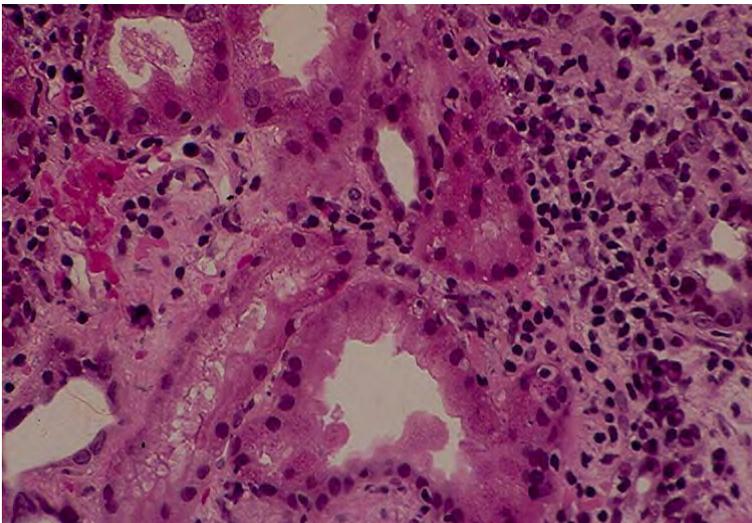

Fig. 5.9. Severe renal tubular injury/ATN showing numerous renal tubular cells in urine sediment (A). The tubular cell cytoplasm expresses vimentin, an important feature (B). (A: Pap, x 400; B: ABC, x 400).

Acute glomerulonephritis and *Acute interstitial nephritis*. The urine cytologic findings in these two conditions have been previously discussed.

Acute Renal Transplant Rejection may occur any time in patients with renal transplant. The urine sediment in this situation shows evidence of a renal tubular injury that is characterized by an increased number of RTCs, several CD4 and CD8 positive T-cells, RBCs and RBC casts. (Fig.5.10).

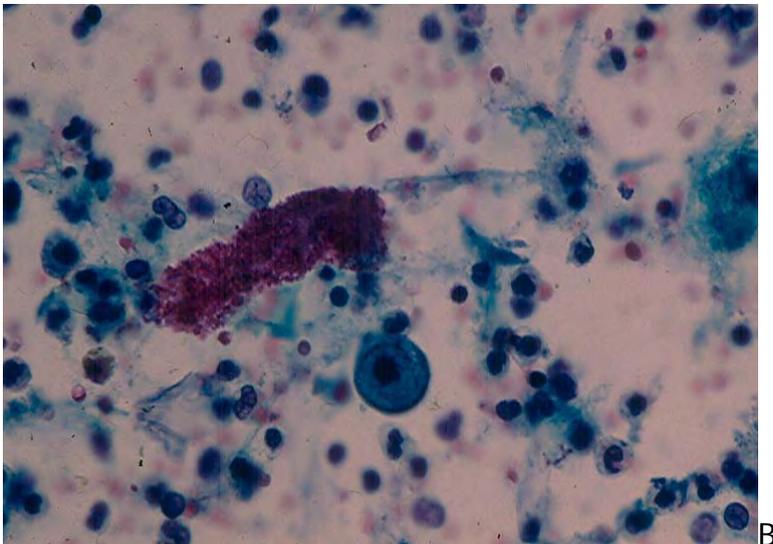

Fig. 5.10. Acute renal transplant rejection:
 A. Histologic picture of a lymphocytic tubulitis. (HE, x200).
 B. Urine showing numerous lymphocytes, RBCs and an RBC cast. (Pap, x400).

An acute renal transplant rejection may mimic a polyomavirus nephritis clinically and histologically. A polyomavirus nephritis may show renal tubular cells with characteristic nuclear features of polyomavirus infection. The diagnosis may be further confirmed by immunostaining of the abnormal tubular cells with a commercially available polyomavirus antibody or by identification of 40-50-nm icosahedral virus particles in the sediment of a negative urine (negative for cells with changes characteristic for polyomavirus infection) by electron microscopy. A rapid and accurate diagnosis of acute renal transplant rejection is very important, as the therapeutic approaches are different: increased immunosuppression for rejection and decreased immunosuppression for polyomavirus nephritis.

CHRONIC RENAL FAILURE

Chronic renal failure is characterized by a progressive azotemia over weeks or months. The patient usually has isosthenuria and hypertension. Both kidneys are small on ultrasonography or CT scan, and radiologic evidence of renal osteodystrophy is present. It is secondary to renal glomerulopathies, tubulointerstitial nephritis, polycystic kidneys, Alport syndrome, obstructive nephropathy and hypertension. The patient's urine sediment may show a few broad casts, and RBCs and RBC casts may also be seen. Dysmorphic RBCs are usually not seen even in patient with a prior history of renal glomerulonephritis.

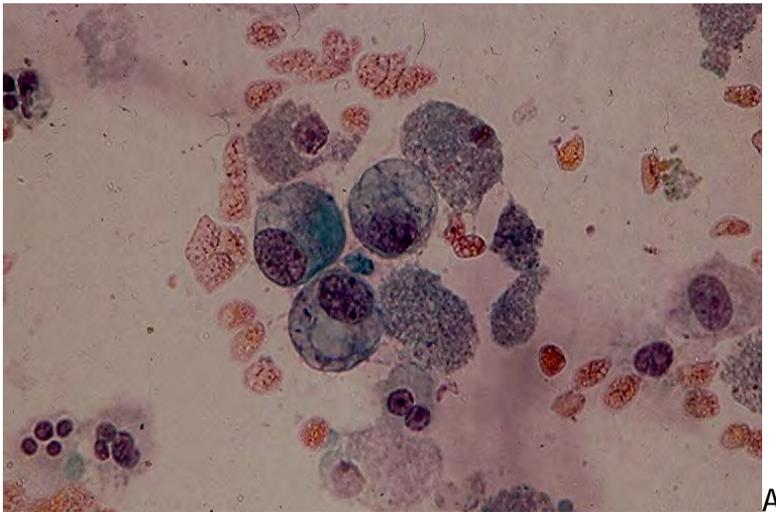

RENAL TUBULAR INJURY AND REPAIR TUBULAR CELLS

Renal tubular injury of mild or moderate degrees is common and usually asymptomatic. It is

caused by numerous reasons including ingestion of some foods, chemical substances or drugs with nephrotoxic effects. Examination of the patient's urine sediment will reveal an increased number of RTCs.

Renal tubular injury has been arbitrarily classified as mild, moderate and severe by Schumann based on the number of RTCs present in 10 high power fields (x 40 objective). A diagnosis of a mild or moderate renal tubular injury is made when the number of RTCs is greater than 50 or between 100 and 200, respectively. When the number of RTCs is greater than 200 a severe renal tubular injury is present. Injured RTCs are replaced by repair RTCs that develop from residual RTCs within renal tubules.

Repair RTCs are large and measure up to 100 microns in greatest dimension and display regenerative changes that are characterized by cytoplasmic basophilia, enlarged and hyperchromatic nuclei, prominent nucleoli and occasional mitoses; and intracytoplasmic vacuoles may be observed. Repair RTCs may occur singly but more often in small clusters of 10 to 20 cells with acinar arrangement. Nuclear pleomorphism may be present. Repair RTCs may be mistaken for malignant glandular cells by an inexperienced observer. Usually repair RTCs in the same specimen display a spectrum of nuclear changes ranging from mild to severe atypia with a variable degree of nuclear pleomorphism, hyperchromasia and chromatin clumping. Conspicuous or prominent nucleoli are usually present. (Fig. 5.11).

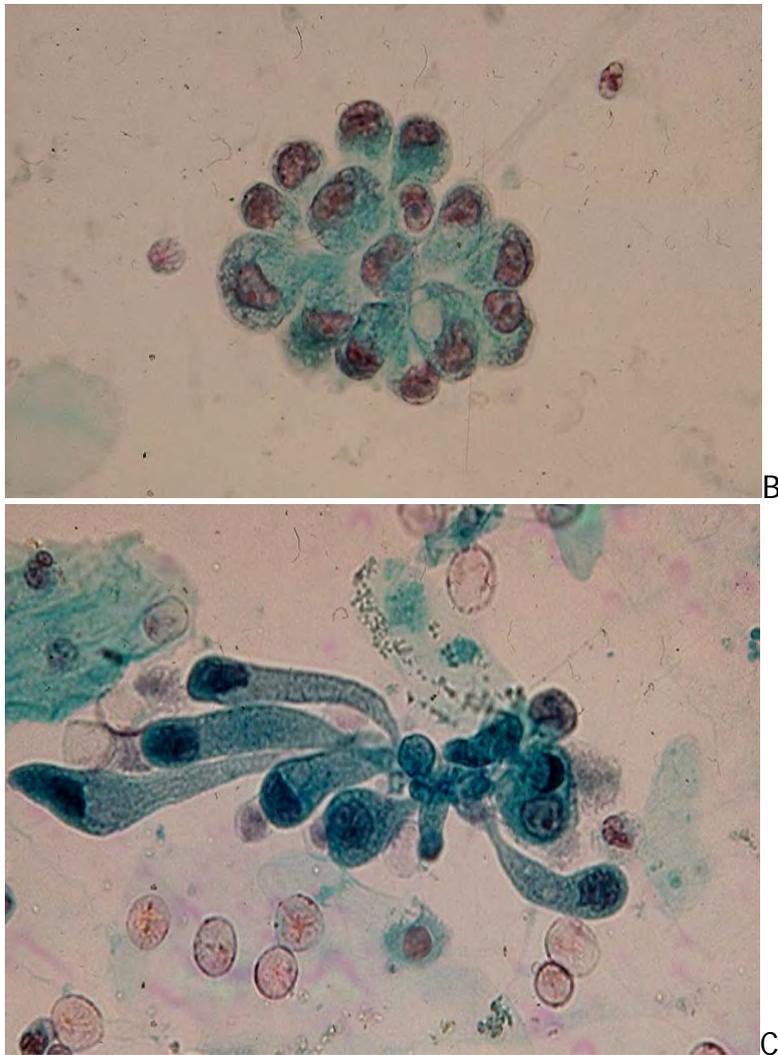

Fig.5.11. Repair renal tubular cells:

A. An aggregate of repair renal tubular cells (RRTC) showing basophilic or vacuolated cytoplasm, oval nuclei and conspicuous nucleoli.

B. A group of RRTCs with prominent nucleoli forming a rosette.

C. A cluster of RRTCs with some having a columnar configuration with tapered cytoplasm.

(Pap: A, B, C, x 500)

Repair RTCs express cytokeratin and vimentin while normal urothelial cells are negative for vimentin. (Fig.5.12). Expression of vimentin is a feature of regenerative and damaged RTCs. These cells should be differentiated from those of a renal cell carcinoma that also express cytokeratin and vimentin. Renal cell carcinoma cells express, in addition, renal cell carcinoma antigen that can be demonstrated by immunocytochemical staining. Clinical and diagnostic imaging findings will provide additional information to rule out a renal tumor.

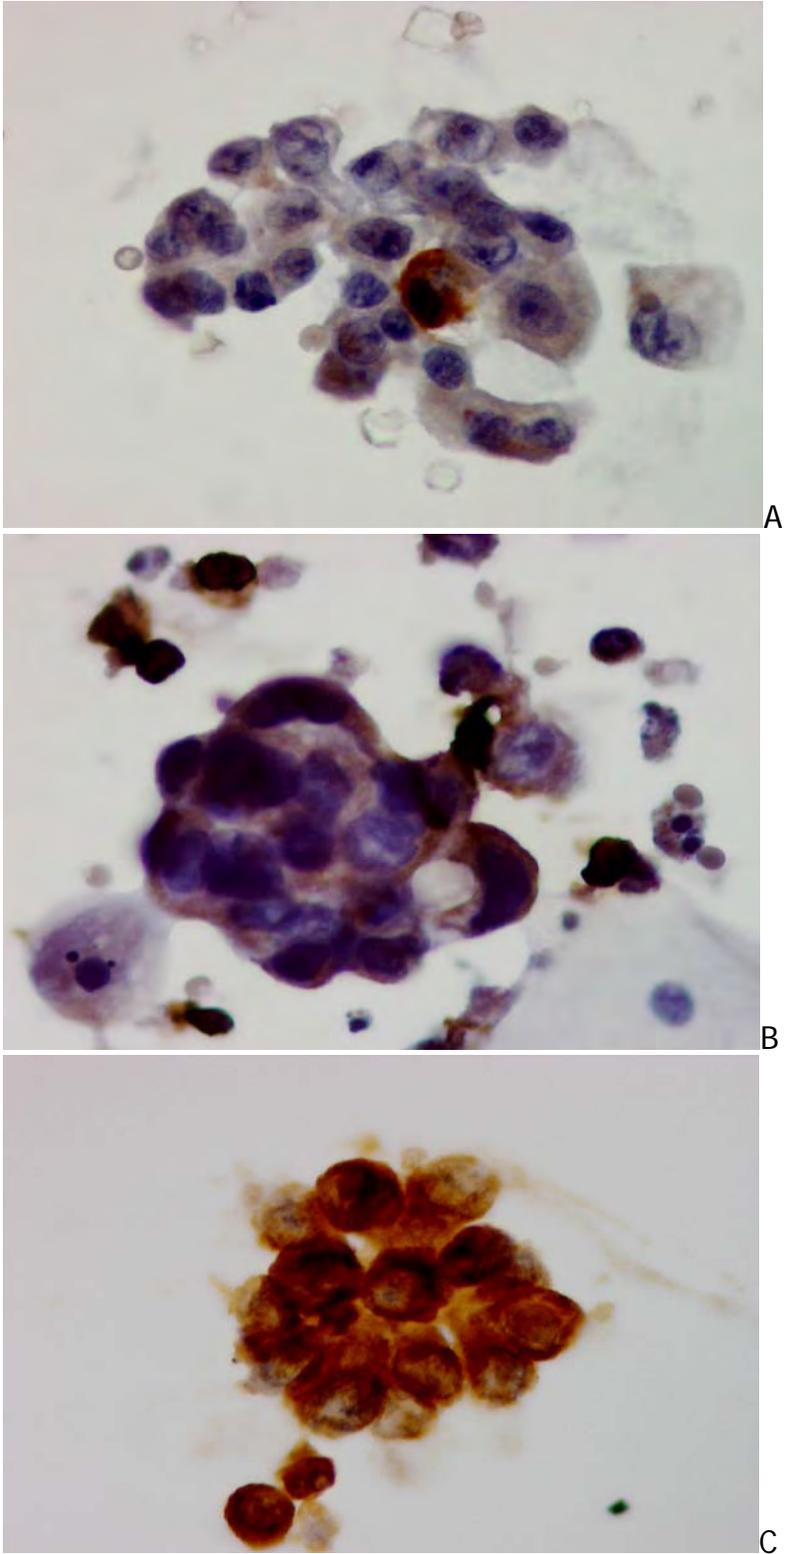

Fig. 5.12. A to C: Clustered pleomorphic RRTCs with prominent nucleoli showing a positive cytoplasmic staining reaction to vimentin antibody (ABC stain on cells previously stained with the Papanicolaou method, x 500)

OTHER CONDITIONS

Fungal casts may be found in urine sediments of patients with renal candidiasis. (Fig.5.13). Clusters of renal tubular cells with yellow bile-stained cytoplasm may be found urine of a patient with severe jaundice and hepatorenal syndrome. (Fig.5.14). Malakoplakia is a rare chronic granulomatous disease that may affect the lower urinary tract and kidney. Cases with malakoplakia involving the renal parenchyma presenting with acute renal failure and fever of unknown origin, have been reported. Macrophages with intracytoplasmic round Michealis-Gutmann bodies may be identified in those patients' urine sediments. (Fig.5.15).
